$$\cdot4839 : 2{\cdot}920$$

or as

$$1 : 6{\cdot}034.$$

From this it appears that the specific resistance of commercial iron such as is now used is 6·034 instead of 6·558, as usually given in text-books.

The specific resistance at 60deg. F., or the resistance in absolute C.-G.-S. units of a centimetre cube is as follows:—

Silver	1·609
Copper	1·642
Pure Iron.....	9·7535
Commercial Iron	9·907, instead of 10·769.

Pure iron at 0deg. C. is taken at 5·94 times that of pure cop-

per (Matthiessen, *Proc.* R. S. 1863, p. 472). If, therefore, we take Matthiessen's figure as the resistance of pure iron, the wire now supplied has a conductivity of 98·44 per cent. of pure iron.

The temperature coefficient was obtained on another length of the same wire.

TEMPERATURE COEFFICIENT. TESTS OF IRON WIRE.

Temperature Centigrade.	Resistance.		Remarks.
	Measured.	Calculated.	
Degrees.	Ohms.	Ohms.	
17	10·83	10·83	Length of wire, 293 feet.
20	11·03	10·99	Weight of wire, 8,807 grains.
25	11·23	11·25	Diameter of wire, 40 mils.
30	11·53	11·53	
37	11·93	11·92	
41	12·13	12·15	$Rt_1 = R_t (1·0043)^{t_1 - t}$.
48	12·53	12·57	
53	12·83	12·87	
59	13·23	13·25	
65	13·63	13·63	
73	14·13	14·16	
80	14·63	14·65	
86	15·03	15·08	
92	15·43	15 52	
95·5	15·73	15·78	
97·5	15·93	15·93	

The following figures will be found useful:—

1 foot grain of pure iron	1·097 ohm
1 metre-gramme of pure iron	0·7654 ohm
1 ohm-mile of pure iron	4368·94lbs.

Knowing the ohm-mile of any iron wire which is obtained by multiplying the weight in lbs. per mile by the resistance per mile we readily get the percentage of conductivity of pure iron of that wire.

DISCUSSION.

Sir WM. THOMSON: What is the difference between the percentage of ordinary iron and the purest iron? And again, is it a commercial difficulty to get iron of the very highest conductivity that iron gives, or is it relatively as easy as it is to get copper of the best conductivity?

Mr. PREECE: There is little difference in copper.

Sir WM. THOMSON: Well, the price of high conductivity iron and good mechanical qualities will be very large in comparison with that of iron having much less conductivity?

Mr. PREECE: The difficulty of getting this pure iron is very great, but it is an £.s.d. difficulty. The price of the best conductivity iron wire runs to something between £15 and £20 per ton—that is, taking the iron at 98 per cent.; but if you are satisfied with iron at 90 per cent. it makes a difference of £5 or £6 a ton, and hitherto we have used this pure iron in the Post Office service in order to secure high efficiency in working. That is now being secured by copper. Copper is going to oust iron out of the field, and I think the necessity of paying this high price for high conductivity iron has diminished very much.

Sir WILLIAM THOMSON: I see that in the table purest iron is quoted at 97½ and commercial iron 99, so that there is only 1½ per cent. difference; but the difference between commercial copper of different qualities, such as were used in cable-making work before the year 1858, was as much as from conductivity 30 to conductivity 100. A great deal of the wire that was put into submarine cables at that time was of only 35 conductivity, and a rough average of the different copper wires sent in for making submarine cables was about 70 instead of 100, and at the present time the non-conductivity copper will be found to be not more than a half, and sometimes less than a half, of conductivity copper.

Mr. PREECE: This is only a comparison between the best commercial iron and pure iron. The ordinary iron that is used is very much below this indeed, and there is quite as much difference between ordinary iron and this form of it now as there was between the coppers in the days you speak of.

Sir WM. THOMSON: Then some of the iron wire may have the conductivity required.

Mr. PREECE: There is plenty of iron wire which gives as much as 15 ohms per mile. This gave 12.

Prof. S. P. THOMPSON: Will Mr. Preece be good enough to tell us something about the chemical analysis of this iron? One knows that the electrical deposits on iron must be presumably purer than other deposits, and that such iron has many different properties in many respects than iron produced by ordinary processes.

Mr. PREECE: I gave that information in a paper which I read before the Institution of Civil Engineers in 1884 or 1885, and this paper is the outcome of that paper. It gave the analyses of various classes of iron wire, but it was wanting in the particular information that this paper supplies; but Prof. Thompson will find the information he wants there.

Sir R. BALL (the President): I should like to ask Mr. Preece what was the weight of the iron wire a mile long at an ohm resistance.

Mr. PREECE: 4,368lb.

Sir R. BALL: Two tons practically?

Mr. PREECE: Yes, very nearly.

Sir R. BALL: Iron wire a mile long and two tons weight has an ohm resistance.

Mr. PREECE: I might mention that, knowing the weight to the ohm-mile, you have the resistance per mile of any other weight. For instance, we have got a mile of wire of any given weight; divide 4,368 by 400, and you have the resistance per mile.

ON THE INFLUENCE OF A PLANE OF TRANSVERSE SECTION ON THE MAGNETIC PERMEABILITY OF AN IRON BAR.*

By Prof. J. A. EWING, F.R.S. (University College, Dundee), and Mr. WILLIAM LOW.

It has been remarked by Prof. J. J. Thomson and Mr. H. F. Newall, that when an iron bar is cut across, and the cut ends are brought into contact, the magnetic permeability is notably reduced.†

Our attention was drawn to the matter in experimenting by the "isthmus" method described in former papers, when we attempted to use, instead of a solid bobbin, a short cylinder for the narrow central neck, separated by transverse planes of section from the conical ends. We found that even when such a cylinder was placed in close contact with the ends of the cones the induction in it was much smaller than in the neck of a solid bobbin of corresponding size; and we were forced to ascribe this defect of permeability to the fact that the induction was being measured at a place only a little way from two planes of transverse section. To examine the influence of transverse section more fully, and to see how far that influence is modified when the pieces are pressed against one another, we made a separate series of experiments, in which the permeability of cut and uncut wrought iron bars was determined by a method similar to that used by Dr. J. Hopkinson.‡

The bar to be tested was let into a massive rectangular yoke of wrought iron, forming a double path for the return of the lines of induction from end to end.

The effect of this is to get rid in great measure, though not completely, of the self-demagnetising influence of the bar's ends, so that the metal may be tested in a condition approximating to endlessness. The ends of the bar were sunk into holes bored for them in the yoke; one abutted against a fixed stop, on the other a plunger rested which was carried through the yoke, and could be loaded on top by means of a lever so as to produce a stress of compression in the bar.

The clear length of the bar between the inside faces of the yoke was 12·7 cms. Its area of section was 0·494 sq. cm., and that of the two sides of the yoke, taken together, was 51 sq. cms. The bar was wound along its whole clear length with a magnetising solenoid, through which currents of various strengths were sent from a battery of accumulators.

The magnetic induction was determined by reversing the current in this solenoid, and observing the transient current induced in an induction coil less than 1 cm. long wound at the middle of the bar.

The results can be stated here only very shortly. First a solid wrought iron bar was tested without compression, and then under a compressive stress of 226 kilos. per sq. cm.

Then the bar was cut into two parts at the centre and tested again, with and without the same load. Again it was cut into four parts, and finally into eight parts, and was tested with and without load in each case.

Each cutting caused a notable loss of permeability. The following are the values of the maximum ratio of magnetic induction ($\mathfrak{B}$) at the middle of the bar to the magnetising force due to the solenoid when the bar was tested without load:—

Solid bar	1220
Bar cut in two.....	930
Bar cut in four	640
Bar cut in eight	400

* Abstract of Paper read before the British Association Meeting at Manchester, September, 1887.

† *Proc.* Camb. Phil. Soc., Feb., 1887.

‡ Magnetisation of Iron, *Phil. Trans.*, 1885, Part II.

Digitized by Google

The effect of loading was very remarkable. The curve of $\mathfrak{B}$ and $\mathfrak{H}$ in the solid bar is depressed by compressive stress with moderate values of $\mathfrak{H}$—that is to say, the bar is less susceptible to magnetisation under compression. The same effect is seen when the bar is cut in two. When the bar is cut in four, loading produces almost no change in the susceptibility, and when the bar is cut in eight loading produces a marked *increase* of susceptibility. Subjecting a cut bar to compression has two antagonistic effects on its magnetic permeability; it reduces the permeability by its effects on the solid portions; it increases it by its effect at the places of section; and, when these are numerous enough, the second or positive effect swamps the first or negative effect.

Next, another bar was tested (with and without load)—first when solid; then when cut at the middle into two parts, the cut ends being in the ordinary state as they left the lathes; and lastly, with the cut ends carefully faced up to the condition of true planes by scraping and comparing them with a standard Whitworth plane. So long as the bar was not loaded the magnetic susceptibility in the second or rough-cut state was much the same as in the third or faced-true state; in both it was notably less than before the bar was cut. But when the load was applied a remarkable difference was exhibited. The rough-cut bar, as in the former specimen with one cut, had its susceptibility reduced by compression; the faced bar, on the other hand, suffered no material change. The curves of magnetisation and field for (1) the rough-cut bar without load, (2) the faced bar without load, (3) the faced bar with load, and (4) the solid bar with load, are all nearly coincident. This result was confirmed by independent experiments with another sample.

When the ends of the cut bar were faced true the two effects of compression (by the particular load used in these tests) practically neutralised each other; when the bar was rough cut the negative effect was the stronger. The chief result of facing the ends is to augment the positive influence of the load. When loaded the bar with faced ends is, in fact, almost undistinguishable as to its magnetic permeability from the same bar in the uncut state.

The influence of a plane of section may be demonstrated by comparing the magnetic induction through and close to the plane of section of a cut bar with the induction in parts of the bar lying at some distance, by slipping an induction coil along the bar. In our experiments, however, this showed only a small part of the whole effect. A comparison of induction measured by means of coils placed at other parts of the length as well as at the middle of the bar, both before and after the bar was cut, showed that a single plane of section at the middle reduced the induction along the whole length to a remarkable extent, though its influence was of course most marked in the portions nearest to the plane of section.

The results make it highly probable that the effect of a plane of section in reducing the permeability of an iron bar is wholly due to a film of air between the cut faces. Using the method which Hopkinson has employed in predetermining the induction in dynamo cores, in which the line-integral of the magnetising force is equated with the line-integral of the induction divided by the permeability, we have calculated the thickness of air-film required to account for the defect of induction which we have observed. We find that when a cut bar is exposed to a magnetising force of 10 C.-G.-S. units, the air-film must have a thickness of only 0·028 mm. to explain the loss of permeability. And when the bar is cut into 4 or into 8 parts, the whole defect of induction is completely accounted for if we suppose each cut to introduce an air-film of about this thickness. Under stronger magnetising forces the thickness of the supposed air-film is reduced, as we should expect, so that when the magnetising force is about 50 C.-G.-S., the thickness of the film is only 0·014 mm., or half the above.

DISCUSSION.

Mr. GLAZEBROOK said he happened to have a proof of a paper on a similar subject by Prof. J. J. Thomson, and he might as well put the figures of the latter on the board, so that they might be compared with those of Prof. Ewing. In those experiments a bar of iron 10 cm. long was employed, which was cut in two; the ends were turned in a lathe roughly, then worked with a true plane as near as could be, and then Prof. Thomson made observations of the same kind as those of Prof. Ewing, separating the ends by one-hundredth of a diameter, two-hundredths, and so on. He would take one of the numbers on the board, referring with a magnetising force of 200, which he (Mr. Glazebrook) thought was stronger by four times than Prof. Ewing's. Taking that case only with a continuous core, the induction observed was 6,048. With the ends cut and turned in a lathe, then worked up to a true plane and pressed together with a wooden clamp, the induction came to be 5,472. With the ends turned as plain as they could be got the induction was 6,000, and with the ends separated by one one-hundredth of a diameter it was 5,328. Prof. Thomson said in the conclusion of his paper that the results were just as might be got if Green's expression were taken for the distribution of magnetism on a bar or cylinder placed in a uniform magnetic field.

Prof. PERRY: Was there iron connection between the ends?

Mr. GLAZEBROOK: There was no iron connection between the ends.

Lord RAYLEIGH: Is there any estimate of the air space required to explain the results?

Mr. GLAZEBROOK: There was no estimate.

Sir WM. THOMSON said what occurred to him as of some interest in connection with the physical properties concerned was that when the ends, pressed together, were not perfectly true the stress would be enormously deficient in different parts, and they knew that the effects of stress on magnetism were far from being in simple proportion to the pressure. Stress very intense in one part and not so intense in another would produce a very different effect from the uniform stress which existed in different parts of the iron. That, no doubt, would produce some complication in estimating the effects of stress which Prof. Ewing described. One question which he would like to ask was, was there any effect of instability, or anything to prevent the effect of instability?

Prof. EWING: As a matter of fact the bar was enclosed in a paper tube, which was enclosed in a solenoid of thick wire. It was perfectly stable.

Sir WM. THOMSON said it would be exceedingly interesting if Prof. Ewing would, with his apparatus, repeat the experiment, introducing a thin film of gold leaf. He (Sir William Thomson) had almost no doubt the result would be negative, but still it would be satisfactory just to know whether magnetic contact between iron and iron was or was not necessary. There was one other little point of interest. Was it possible to have in air or in gold leaf such an exceedingly intense field as 50,000 C.-G.-S! The field of the so-called induction—that was to say, the magnetic force on an ideal of the unit of the pole in a slot perpendicular to the lines of force, had been raised to a value not far from 50,000 in some of Prof. Ewing's experiments, by far the greatest figure ever attained. He had on a previous occasion inadvertently said that luminiferous ether had nothing to do but transmit light, but it must also be capable of exhaustion of energy at the rate of 50,000 times 50,000, 2,500 million C.-G.-S., or 2,500 million ergs. per centimetre, so that if there was to be any kinetic theory of the ether whatever, which was to be anything more than a mathematical abstraction, it must be shown to be capable of having its energy reduced or exhausted at the rate of 2,500 million C.-G.-S. per cubic centimetre. There was something very interesting indeed in estimating the extreme limits of magnetic force actually obtained. They had a limit of magnetisation in iron. Had they or had they not an absolute limit to the amount of magnetic force transmissible through air or gold leaf or a vacuum? He thought to solve that question would be splendid work.

Prof. SILVANUS THOMPSON asked if Prof. Ewing had tried whether after the diminution of the pressure the film of air left between the two pieces of iron remained in a good magnetic state. The question was a little important to those who built dynamos, for it made a very great difference in the making of the magnetic circuit. It might be well to put dynamos together under pressure, unless the film between the pieces could be put back again.

Prof. WIEDEMANN said it would be very interesting to remember an experiment made in the beginning of the century. The experimenter, when magnetising an iron or steel bar by drawing a magnet over it, put a very thin film of oil over the bar. He could not then get magnetisation. When he took off the oil the bar was immediately magnetised.

Mr. A. P. TROTTER said that this was a very important matter for dynamo makers. He had found in calculating the magnetic resistance of the field-magnets of dynamos that the resistance of the joints had to be allowed for. He had endeavoured to reduce this resistance to a minimum by accurately working the surfaces by scraping and the use of surface plates. A considerable amount of high-class workmanship had been expended in this direction, with the hope that the resistance of the joint would be reduced. When the question arose in the design of a new machine as to the probable effect of increasing the number of joints, an experiment was tried to determine the resistance. The upper bar of an inverted single horseshoe was separated from the side bars, first by the thickness of a sheet of paper, then by greater distances up to an inch. It was found that the increase of resistance was simply proportional to the distance, being merely the resistance of the air. No rapid decrease was found, as was expected, when the distance was small, and hence it was assumed that special pains in accurately surfacing the joints were not required. From knowledge of the resistance of the different qualities of iron employed he found the resistance of a joint between wrought iron and wrought iron to be equivalent to about 8 inches run of bar of the area of the joint. The same value was assumed for wrought iron and cast iron, and he had found that letting the end of a bar of wrought iron into a well fitting hole of a depth equal to its diameter produced no perceptible diminution of the resistance of the joint. Considering the large surfaces with which the dynamo maker had to deal, compared with the area of the bar used by Prof. Ewing, and the great force which was found necessary to produce perfect magnetic contact, Mr. Trotter was of opinion that it was useless for the dynamo maker to hope to introduce any improvement in this direction, either by accurate workmanship or by tightly screwing the bars together. Dynamo makers

Digitized by Google

were none the less indebted to Prof. Ewing because this knowledge was of a negative character, for it would leave them with one less direction in which to work in improving their machines.

Lord RAYLEIGH asked Prof. Ewing if he had rightly understood him as to the thickness of the film necessary to explain the magnetic effects of a joint. It seemed to him from the figures given that it would come to about one thousandth of an inch. One could hardly suppose that two reasonably good surfaces in contact would be separated by such resistance as that. It was about forty wave-lengths of light.

Mr. R. P. SELLON said, with regard to the necessity for true joints, speaking as a practical dynamo builder, he thought the explanation of the fact that in dynamos they were not able to find any material difference if the surfaces were very smooth or tightly clamped together, was that the whole resistance between the magnetic limbs and the frames or yokes of the dynamo was very small indeed when compared with the resistance between the pole-piece and the armature. In the case of the Brush machine, he had actually tried the experiment of loosening or slackening away the bolt which held the magnetising limb on the frame, and there the limb was simply dependent upon a single bolt; but he had found that it was possible to slip away the bolt very materially indeed, so that one might imagine that there was a film of air between the surfaces.

Mr. ESSON said it was evident from Prof. Ewing's curves that the difference made in the permeability by increasing the pressure between the joints depended entirely upon the degree to which the magnet was saturated; whereas the difference at the beginning of the curves with low degrees of saturation was quite conspicuous, when the magnet was pretty well saturated the difference was inconsiderable. In dynamo machines they worked with the magnets fairly well saturated, and the working of the joints to a true plane consequently became a matter of small importance. The advantage to be derived from such nicety of workmanship would not nearly compensate for the extra work involved.

Mr. LOVE said the method he had adopted had been by using a circle of iron, so as to get as good a contact as he could. After doing that he had experimented to find the permeability of the iron—first, when the ends were firmly pressed in contact, and after that, when they were separated by known intervals. The resistance of air-space thus made was proportional to its length. Then, with regard to Prof. Ewing's curves, he had made an experiment in which he got an air-space of about a quarter of a millimetre wide. That seemed to answer pretty much to Prof. Ewing's calculation of the value of air-space in the place where he cut his bar into eight pieces. As far as he could see, looking at the curves from the position in which he was standing, his curve was almost exactly identical with Prof. Ewing's in every respect with regard to shape, and, as far as he could remember, as regards height, too. But between zero and the lowest part of the curve, for inductions of 0 to 2,000, the curve entirely changed in shape, becoming concave upwards.

Prof. FITZGERALD said, with reference to the remark of Lord Rayleigh, that it was true that two pieces of glass could be put together with facility, so as to leave an air space of no more than a few wave-lengths. He thought at the same time that anyone experimenting with flat pieces of glass without the application of pressure would not reduce the air-space to so small an amount by any means. It was necessary to apply very considerable pressure before the layers of air would be squeezed out from between them. It was also necessary to take great care in treating the surfaces of glass if they did not want particles of dust to remain between them. He would like to ask Sir William Thomson why he did not in his paper on the previous Thursday lead them to expect an energy per cubic centimetre of 1,000 million million million units? Possibly the remarks he had made that day were intended to lead them up, so that they might not be frightened by the enormous number he was going to mention afterwards.

Prof. EWING, in reply, said Sir William Thomson had asked whether there was any evidence of a limit to the possible number of lines of force per square centimetre of air, and what was the highest number that had been reached. The greatest number of lines of force in air Mr. Low and he had obtained was between 25,000 and 26,000 per square centimetre. There was nothing whatever to indicate that there was any serious difficulty in getting as many more as might be desired. If there was any physical object in forcing more lines into air to see how far they could go, no doubt they could do it with a slight modification of their present apparatus. Prof. Silvanus Thompson asked whether the film of air between the carefully-faced surfaces reappeared after the stress was removed. In their experiments it did so, but that might have been due to the fact that they always gave the bar a strong magnetic shaking up before measuring the induction. Each measurement of induction was made by reversing the magnetic state of the bar, and, in order to get rid of previous magnetisations, they reversed the magnetism many times before each reading. Of course this must have given the bar a powerful magnetic shaking up, and he had no doubt that would be of itself sufficient to account for the reappearance of the film of air. Mr. Trotter had referred to the application of this matter to the joints in dynamos, between yokes and cores and so forth. Curiously enough there appeared to have been for some time a very general impression in the minds of dynamo makers that there was a surface resistance to magnetisation. He had come across this impression even before Prof. J. J. Thomson's discovery was published, and he was at first inclined to regard the impression as an incorrect one, but it was not so; it was perfectly correct that there was a surface resistance, probably due to the distance between the metallic surfaces. But, as Mr. Sellon had pointed out, this was not a matter of much moment in a dynamo, simply because in another part of the magnetic circuit there was a great deal of air space, and putting a little more at the joints did not make any material difference. Lord Rayleigh referred to the difficulty that such an interval as they were obliged to assume seemed greater than was likely to occur in ordinary joints. He was sorry they had as yet made no attempt to measure the interval directly. He hoped to do so, and to make microscopical measurements as to the interval. He thought they might anticipate such an interval as the 35th or 70th of a millimetre when they considered the process of finishing a bar in a lathe. The end was not properly a plane at all, it was always more or less a cone, so that contact took place between two parts of a cut bar either on a circular ring near the outside or on a small circle inside the bar, and the area of that contact was no doubt materially increased by compression; but still, as these experiments seemed to show, the mean distance was not very much diminished by the compression. As regards the question—whether such a distance between the surfaces could exist in a truly faced plane, he thought they had a good deal of independent evidence that such a distance might be looked for. In the experiment of floating one Whitworth plane upon another, unless they squeezed them and gave them time they would find a marvellously small amount of friction, showing, in fact, that there was a very sensible air film between the two, which was only gradually expelled. Here, again, it might be imagined that the film would have vanished in these experiments, since the pieces were in contact for a considerable time; but he thought the film might have been caused to re-appear by the magnetic shaking which the bar got just before the test was made. Another speaker referred to the form which those curves would take if the experiment were made between zero induction and low values of induction. It was quite true that there they would expect by the air film theory—at least they would expect—the difference between the cut bar and the solid bar to become very much less simply because the permeability of the iron was very much less. He ought to have said that Prof. FitzGerald had anticipated him in answering Lord Rayleigh's question.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In the discussion on Prof. Ewing's paper "On the Influence of a Plane of Transverse Section on the Magnetic Permeability of Iron," it did not occur to me that the observed resistance of the joints may be expressed by a certain thickness of air. Mr. Ravenshaw has pointed this out to me. The equivalent resistance to eight inches of iron is one ninetieth of an inch of air.

It is quite certain that this is far greater than the mean distance between the surfaces of a well-fitted joint, and this shows that the magnetic resistance is due to some other cause than the presence of a film of air.

The same reasoning may be applied to Prof. Ewing's experiments.—Yours, &c.,

ALEX. P. TROTTER.

Halifax, Sept. 10, 1887.

HISTORY OF THE WESTINGHOUSE TRANSFORMER.

A very interesting letter on the history of the transformer in the United States has been addressed by Mr. W. Stanley to our contemporary *The Electrician and Electrical Engineer*, of New York. Mr. Stanley says:—

It is not my purpose to write of the electrical problems which have been solved, but simply to narrate the practical developments in which I have been interested. Nor do I wish to claim for myself all the credit for what has been accomplished.

In August, 1884, while measuring the vacua of my incandescent lamps with an induction coil, I noted the relation between the quantity of current absorbed by the primary circuit, and that abstracted from the secondary coil, when the external resistance of the secondary circuit was varied. I found that the ohmic resistance of the primary coil (a thick, short wire) was insufficient in itself to account for the difference of potential maintained at its terminals, and that the *apparent* resistance of this coil varied coincidently with variations of resistance in the secondary circuit.

As these phenomena were analogous to the counter E.M.F. developed by an electric motor, and as they varied in a precisely similar way, I used the term counter E.M.F. at that time to express the reactive effects observed. The relation of this counter effect to the applied E.M.F., and particularly its value as an immaterial variable resistance, I explained at the time to a number of my friends, and shortly afterwards undertook the formation of a system of distribution, having a high difference of potential in the main circuit and induction coils, or converters, as I called them, with which to reduce this difference of potential. My first endeavours were to apply a direct current to a converter wound with a double primary circuit, having an automatic switch to shift the applied E.M.F. from one coil to the other, together with various short-circuiting devices, intended to produce a variable field around the primary and secondary circuits; all these devices proved to be impracticable. My next endeavour was to employ an alternating generator and converters arranged in series in a manner similar to the system of Messrs. Gaulard and Gibbs, of which, however, I knew next to nothing. These coils at first caused much trouble from want of regulation, but I found that, *by saturating the core*—that is, by making the number of ampere-turns sufficiently

Digitized by Google

great and the self-inductive capacity relatively small—I could obtain excellent self-regulation on a constant current circuit. This system, however, wasted a large percentage of the energy applied, and was therefore abandoned.

In my next experiments I used the parallel system of distribution, and immediately found all the previous obstacles removed.

The parallel system, the usefulness of which appears to have first been suggested by Mr. Kennedy (although his experiments were unknown to me when I began work in the same direction), is the natural sequence of any experimental work with the series system; for, as I found, if all the converters had their primary circuits in series, and their secondary circuits connected in parallel, then applying a constant E.M.F. to the primary circuit, a constant difference of potential was obtained from the secondary circuit. The experimental proof of this proposition at once developed the utility of such a system, and the construction of the necessary apparatus for generating and transforming currents of high potential required but the application of previously acquired knowledge.

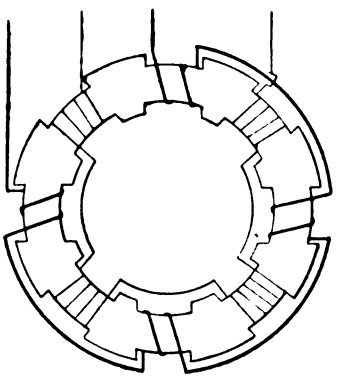

Fig. 1.

In working out a commercial transformer, I began with the Faraday ring type. By adding projecting lugs or teeth, as in a Gramme [Pacinotti] armature (Fig. 1). I somewhat reduced the magnetic resistance. I then applied internal and external rings (see Fig. 2), to reduce the length of the magnetic circuits; this form, however, was inconvenient to construct, and was abandoned almost immediately in favour of the type at present used (Fig. 3), [see also detailed description in *The Electrician*, Aug. 26, 1887], which is a development of the Gramme ring type of converter, for it is simply one coil of a Gramme ring with its inner and outer sheathing of iron.

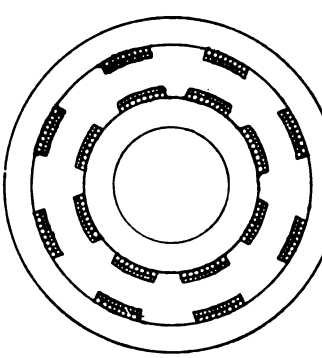

Fig. 2.

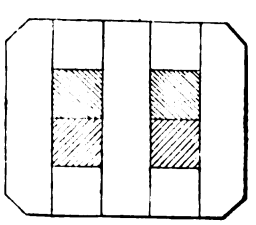

Fig. 3.

In the fall and winter of 1885 I established a central lighting station, employing these converters, at Great Barrington, Mass. This, I believe, was the first station in America operated on the induction system. We fed about 150 incandescent lamps on a circuit of No. 6 (B. and S.) wire, the circuit being nearly a mile in length. The lamps were largely used in the village stores and for general lighting. So successful was this attempt that the Westinghouse Electric Company immediately undertook the construction and installation of a large number of stations upon the same general plan.

The advantages obtained by a double conversion system are very great. In such a system the cost of the conductors, and, more important still, the loss of potential in the line, even for very long distances, may be substantially disregarded. In order to do away as nearly as possible with the loss in conversion that is due to what may be termed magnetic friction I have designed a system which I believe to be entirely novel. In this I employ what I term "auto-converters," viz., converters or transformers, each consisting of a single coil only.

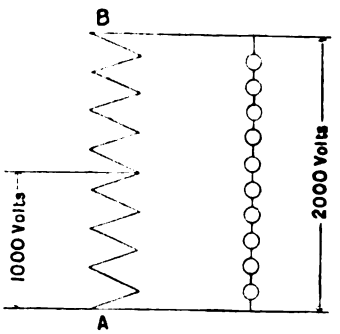

Fig. 4.

Fig. 4 shows one method of raising the potential by means of the "auto-converter." A B is a converter consisting of a single coil. It is evident that one-half of the coil acts to the other half as the primary of an induction coil to its secondary, and the potential between A and B is constant and is double that of A C. Fig. 5 shows an auto-converter for reducing the potential economically, *i. e.*, with less loss than with a double coil transformer. At intermediate points C' D' E' of the single coil A' B' loops are left out from the coil, and from these loops service wires are run, between which translating devices are connected in parallel in the usual manner.

It is evident that if the resistance between adjacent loops is equal, the arrangement becomes a series multiple coupling, and the coil A' B' has no work to do, and consequently there is no loss due to conversion. If, however, the resistance between any two adjacent loops is varied, say, for instance, increased, then that portion of the coil A B included between those loops acts as a primary to the rest of the coil, and the potential difference between all the loops remains constant. From this it will be seen that the coil acts to supply an induced current only to such resistances in any loop as are less than the resistance of the neighbouring loops, and therefore the loss due to conversion is simply that due to the conversion of the current flowing through the algebraic sum of the resistances of the separate loops.

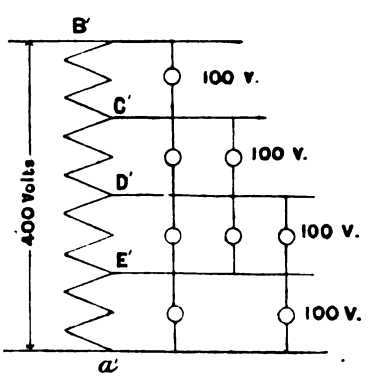

Fig. 5.

This form of converter possesses the same merit in potential distribution that the three-wire system does in the direct system. The real value of the induction system lies in the fact that by it potentials may be varied, raised or lowered at will, in the majority of cases with an accompanying loss of less than 2 per cent., and in many cases with no loss at all. If it were generally understood that the potential applied to a coil is simply distributed over its entire length at an equal voltage per unit of length, and hence that to obtain any desired E.M.F. it is simply necessary to tap off an equivalent length from the coil, the practical applications of the self-induction coil would be far more numerous than they now are.

There is a general misunderstanding to the effect that the

Digitized by Google

alternating system of distribution in this country is, in its details, the invention of Messrs. Gaulard and Gibbs. None of the apparatus now used, however, was either designed or invented by them, nor is the system of distribution employed in connection with two or more converters the series system employed by these gentlemen.

But while the credit of the alternating inductive system, which has now become a commercial success in the United States, cannot be given entirely to Gaulard and Gibbs, their labours have, nevertheless, been most valuable, in that by their persistent efforts towards the practical application of induction coils in electric lighting they have drawn the attention of electricians generally to the subject, and thus paved the way for the new departure in electric engineering.

THE SUPPOSED "NEW FORCE."

BY R. C. SHETTLE, M.D.

(Continued from page 361.)

SPHEROID No. 4.

The wire on spheroid No. 3 was removed, and one half—*i.e.*, 26 strands—reapplied to one half of the surface—*i.e.*, to one half of each hemisphere, on the same side of the spheroid; these wires were laid on with the same description of helical turns as in Nos. 1, 2, and 3, the terminals being taken respectively to the seat of a

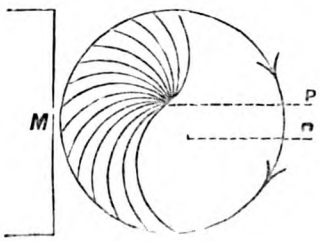

FIG. 8.

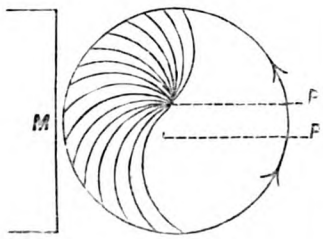

FIG. 9.

north and south magnetic poles on the same side of the sphere. These wires also were secured in position by means of thread.

Experiment 18.—The spheroid was subjected to the influence of the north pole of the electro-magnet just as before. Axial rotation was set up on making battery contact, but only through a limited area; upon making and breaking contact a complete axial rotation, first in one and then in the other direction, could be established.

Experiment 19.—A more precise examination of the motions of No. 4 spheroid showed that the direct and inverse currents had different effects according to the position of the object. Thus, when the spheroid was placed with the terminals of the wires on the left side of the magnetic axis of force (as shown in Fig. 8), the bulk of the wire being on the side of the sphere nearest the magnet, the direct current caused motion to the left, the pole P coming round to P′; but the inverse current in the same position of the sphere caused motion in the opposite direction (see Fig. 9), the pole P coming round to P′.

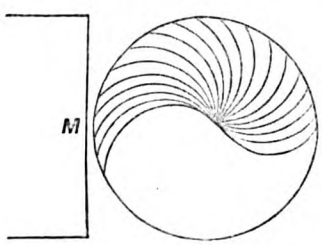

FIG. 10.

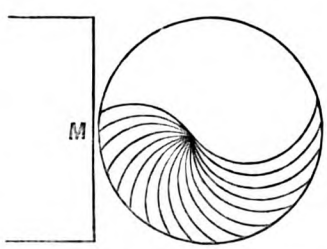

FIG. 11.

Experiment 20.—The direct current when the spheroid was as shown in Fig. 10 was slight, but to the right. The inverse current in the same position of the spheroid caused rapid motion to the right, and brought the poles round to the position shown in Fig. 11.

SPHEROID No. 5.

The surface of a 3in. wooden sphere was divided by an equatorial line into two hemispheres. The central spot on each hemisphere was marked and called a geographical pole; a circle two inches in diameter was drawn round each polar spot, and called a polar circle. The surface was next divided by parallel lines of longitude into six equal parts. The points where the three alternate lines crossed the polar circle were marked, and designed for the seats of three magnetic poles. The intermediate lines of longitude were marked at the point where they crossed the equatorial line. Pins were next driven into each of these nine points, and the sphere was ready to receive its wire coating.

The wire (No. 16 cotton-covered) reached from one of the points on one polar circle to the opposite point on the other circle, taking a diagonal direction from one point to the other, so as to include one of the pins where the next longitudinal line crossed the equatorial line. The terminals and equatorial point were fixed by india rubber insulite. Other pieces of wire were then adapted to the portion already laid on as described, the terminals of each being brought to the same point, until the V shape had been quite filled in its concavity. This plan was adopted for each of the three centres, and is shown in Figs. 12 and 13, 12 being the equatorial, and 13 the polar view.

For the purpose of suspending this spheroid so as to expose a variety of inclinations to the axis of the electro-magnet, loops of whalebone were driven into the points marked with dots on Fig. 13, viz., one at the seat of the geographical pole, and five others between this and two of the magnetic poles.

Experiment 21.—Sphere No. 5 was subjected to the influence of the electro-magnet by being suspended first from the geograp hical pole. Upon making battery contact, axial rotation through about 45deg. was set up; but the motion was very slow, and only occurred after some few seconds of exposure.

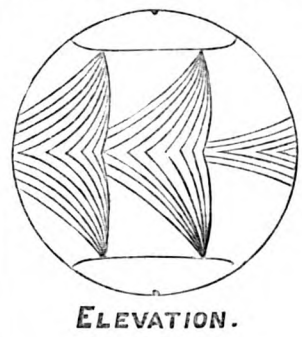

FIG. 12.

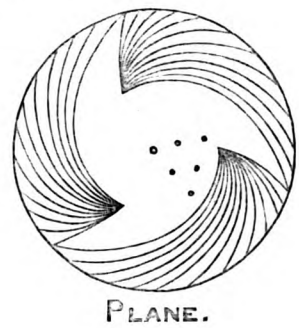

FIG. 13.

Experiment 22.—The inclination of the sphere was changed, the point of suspension being now close to one of the polar points. On making battery contact, axial rotation was quickly set up, and the motion was much more rapid than in Experiment 21, especially as the pole nearest to the electro-magnet was brought more immediately into the axis of force. By maintaining contact the pole nearest the magnet oscillated, and then tended to come to rest opposite the electro-magnetic pole.

(To be continued.)

SCIENTIFIC LECTURES AT THE NEWCASTLE EXHIBITION.

On Saturday last Prof. Garnett again lectured on the electric light in the theatre of the Newcastle Exhibition. A frame was erected on the stage, from which were suspended two arc lamps constructed by Messrs. J. H. Holmes and Co., of Newcastle, two diamond arc lamps employed by Messrs. Woodhouse and Rawson in lighting the garden of the Exhibition, and an incandescent lamp of 600 candle-power constructed by Messrs. Clarke, Chapman and Parsons, of Gateshead. By the side of this frame was an incandescent search light of 500 candle-power lent by the last mentioned firm and employed by ships in entering docks or harbours at night. This light was used on the occasion in question to illuminate some of the darker objects on the stage. A reflecting galvanometer served to show the production of a current in a coil of wire moving near a steel bar magnet by means of a disc of light on the magic lantern screen, and a few magic lantern views and a hand Gramme machine served to illustrate the construction of the dynamo. One of the prettiest exhibits was a small arc light, constructed by Messrs. J. H. Holmes and Co., and burning steadily with a current of two amperes. The lamp was connected in series with two small glow lamps, so arranged that the two absorbed exactly the same amount of energy as the arc lamp, while the light produced could be compared by the audience. On a small drawing room table in front of the stage stood a turbo-electric generator having an output of about 5 electrical horse-power, and lent by Messrs. Clarke, Chapman and Parsons, of Gateshead. Below it were placed the armature, spindle, and one-half of the barrel of a large generator, intended for an Atlantic steamer, and having an output of nearly 40 electrical horse-power. This generator is constructed on the triple expansion principle, the steam, in passing from the centre to either end of the barrel, having to

Digitized by Google

make its way through three sets of turbines of increasing dimensions.

The lecture commenced with a description of the arrangements for the lighting of the theatre, and for raising and lowering the lights as required for stage effects. Three times the theatre was put into darkness as though an accident had happened to the machinery, and on each occasion one of the "panic circuits" was switched on either from the stage or the ticket office outside. One of these panic circuits contains an incandescent lamp of 1,000 candle-power constructed by Messrs. Clarke, Chapman, Parsons and Co., and it was surprising to notice how well the large building was lighted by this lamp alone. All the rest of the arrangements for the lighting of the theatre have been carried out by Messrs. J. H. Holmes and Co., of Newcastle, whose "panic circuit" is connected with the picture gallery lights quite independent of all the other lamps in the theatre. The account which we have given of the apparatus on the stage will convey to our readers a fair idea of what the rest of Prof. Garnett's lecture comprised. There was a full house, the audience consisting largely of working men. Arrangements have been made for scientific lectures every Monday and Saturday evening until the close of the Exhibition.

ELECTRIC LIGHTING FROM CENTRAL STATIONS.*

I.—Electric Lamps.

If I use a galvanic battery or a dynamo machine as a source of electricity, and connect its poles by a metal wire, an electric current flows through the wire. If I break the wire at any point, the current ceases to flow. If part of the wire be wound round a bar of iron, a noise is heard, and a bright momentary flash is seen at the instant of breaking the circuit. If the iron bar be U-shaped so as to form an electro-magnet of the usual type with poles, then by causing the rupture of the wire to take place between the poles I can increase enormously the noise and momentary character of the flash.

If, on the other hand, the wire be not coiled and has no iron near it, the act of breaking the wire does not give rise to noise, and the flash is not so instantaneous; in fact, the flash can be rendered permanent by holding the two broken ends at a short distance. I am now using a copper wire. I hold the ends at a distance of one eighth of an inch, and you see a steady green light. I replace the copper by iron, and you see a redder colour. Again, if I use zinc the colour is blue. In each case the heat developed suffices to melt the metal and evaporate it, and the distinctive colour is given off only when the metal is in the form of vapour.

Carbon in the form of charcoal, however, does not melt or evaporate even at a very high temperature. When now I use two charcoal rods in the part of the circuit which I break, we have the brilliant white incandescence of a solid body at the highest attainable temperature. This is what is generally known as the arc light. It was discovered by Sir Humphry Davy at the beginning of the century. Since that time the ingenuity of inventors has led to the introduction of numerous devices for maintaining the distance of the carbons constant. One of the most successful of these inventions is the lamp of Messrs. Brockie and Pell, which I have here, and whose steady bright silent light must please the most critical eye. I throw an image of the carbon points on the screen. You notice that from the carbon connected with the positive pole of the battery particles fly off, and it becomes hollowed into a white crater of brilliant incandescence. On the negative carbon a pile of carbon is heaped up. Both carbons are meanwhile being consumed by the oxygen of the air. Hence a feeding action is required to maintain a constant distance between the points. This is regulated by a simple mechanism, and we have a practical lamp suitable for street lighting, and for the illumination of workshops and large halls or open spaces.

But it is not necessary to sever the metallic conductor in order to get intense heat and light. No substance is a perfect conductor, and the energy of the electric current is partly used up in heating the materials through which it passes. I pass the current through a platinum wire. It glows with intense heat. I increase the current, and the incandescence of the wire is white. I have chosen platinum because the temperature of melting is high, and it is not consumed by the oxygen of the atmosphere But even platinum has a melting temperature, and now when I increase the current still further it melts and the source of light has broken down.

The radiant energy of this wire consists partly of heat rays which are invisible to our eyes, and partly of visible rays. The higher the temperature the greater is the proportion of visible rays. Thus by choosing platinum with its high melting point we have chosen an economical source of light.

Carbon, however, has a higher melting point, and we can obtain fine threads or filaments of carbon. It must therefore be economical. Here I have such a filament exposed to the air. I pass a current through it. It gives a brilliant flash for a second, and is consumed by the oxygen of the atmosphere. Clearly we must remove this defect. I have a similar filament in a glass globe full of nitrogen gas, and now the filament shines as the current goes through it. Of course you would expect the heat to be used up by contact with the nitrogen gas setting up convection currents and cooling the filament. Let us see if this is the case. Here I have an exactly similar filament in a similar glass bulb from which all trace of air or gas has been, so far as possible, exhausted. I pass the same electric current through both. The one with nitrogen gas is dull, the one in vacuo shining with marvellous brilliancy.

This last is the incandescent lamp of the present day, whose mellow light is so pleasing to the eye. It is safe, cleanly, and healthy. Safe, because it cannot set fire to inflammable objects and cannot explode like gas; cleanly, because it has no noxious gases to tarnish silver and decorations; healthy, because it does not pollute the atmosphere, and does not heat it as gas does. Its safety has been shown by the action of the municipality of Paris, who, after the burning of the Opera Comique by gas, ordained that all theatres are to be lighted by these electric lights. Its good qualities are proved by the fact that every one who has the means furnishes his house with this light, and by the fact that the public are crying out at the action of Parliament in hindering the public supply of electricity by legislation in support of the gas monopoly.

You have now seen two methods by which electricity can be utilised for producing the electric light—the arc and the incandescent systems. I do not know of any other that is possible, except that perhaps in the future the brilliant discoveries of Mr. Crookes may be turned to practical account. That eminent investigator has discovered that if an electric current be passed through a glass tube or bulb nearly emptied of air, and if certain substances be placed in the glass bulb, they shine with a brilliant light. You are aware that some substances are said to be phosphorescent, which means that after having been exposed to a powerful light they shine in the dark. I have here six bottles, each containing a different fluorescent substance. I illuminate them for a few seconds by holding them before the light of burning magnesium, and now on darkening the room they give off a feeble light. Visionaries have been known who hoped that some day our houses will all be painted with some such substance, so that the solar energy stored up in the day may return to us a general illumination at night. In the meantime we know that by subjecting such substances to the electric current of great pressure which we get from the induction coil, they do, if enclosed in a nearly perfect vacuum, give off a light far more brilliant than the phosphoresence you have just seen. Through the kindness of Dr. De la Rue, I am able now to show you such brilliant effects, and you will observe that while I am using up the feeble amount of electrical energy supplied by this induction coil, I am producing an illumination which lights up all the objects in the neighbourhood.

We have, however, at present no practical application of these brilliant discoveries of Mr. Crookes.

II.—Generators of Electricity.

Having now glanced at the lamps at our disposal for utilising the electric current, viz., the arc lamp for streets and large halls, and the incandescent or glow lamp for interiors of dwelling houses, let us glance for a moment at the means which we have at our disposal for generating the electric current. There are in general use two ways of generating this kind of energy; the first by transforming chemical into electrical energy, the second by transforming the mechanical energy of water, steam, &c., into electrical energy. The loss in either case need not amount to more than 10 per cent. The apparatus which utilises chemical action is called a galvanic battery, or simply a battery. The best of these are secondary batteries in which, when the chemical energy is used up, it can be restored by charging with those machines which convert mechanical into electrical energy. We have several excellent secondary batteries, the best I know being that called the Union Battery. The Electric Power and Storage Company, and Elwell-Parker both supply a good secondary battery which has long stood the test of experience. Any one of these batteries has two terminals, to which the ends of an electric circuit can be attached, and then an electric current flows through the circuit. When the battery is exhausted, a current is sent through it in the reverse direction, and it is renovated.

All the machines at present used for converting mechanical into electric energy are founded on the discovery of Faraday that by moving about a coil of wire in the neighbourhood of a magnet, an electric current can be started in the coil. The same coil will experience a force tending to move it if an electric current flows through it while it is in the neighbourhood of a magnet. A machine constructed on this principle is usually called a dynamo machine, and it can be used either to convert mechanical into electric energy, or *vice versâ*. I will now show by the aid of the lantern a model of such a dynamo running as a motor when an electric current is passed through its coils.

I do not wish to waste your time by showing the details of dynamo machines. A dynamo contains generally four special parts:—(1) Pieces of iron with insulated wire coiled round them. These are called field-magnets, and are fixed in the framework of the machine or else form part of it. (2) Revolving coils of insulated wire. These form what is called the armature. (3) A commutator consisting of a number of bars of metal connected to the coils and revolving with them. (4) Two wire brushes fixed to the framework, rubbing against the commutator bars. To these last are attached the ends of the conducting circuit through which a current is to flow. Part of the electric energy is generally diverted through the wire coils on the field-magnets so as to magnetise them. The object of the commutator is to convert the electric current, which is reversed in the coils at each half rotation which they make, into a continuous current in the external circuit.

I now throw on the screen an end view of such a dynamo, and you will observe the field-magnets and brushes which are fixed. But by turning a handle you now see the central armature and the commutator on which the brushes rub rotating continuously. You can recognise these four parts in any of the ordinary dynamos. Sometimes, however, there is no object in having a continuous current in the external circuit, in which case the commutator is dispensed with, and the two ends of the wire coils in the armature are connected to two metal rings on and concentric with the spindle. The brushes rubbing on these lead to the external circuit a

* A lecture delivered by Prof. George Forbes, M.A., F.R.S., to working men at the Manchester Meeting of the British Association, September 3rd, 1887.

Digitized by Google

current which is reversed in direction at each passage of the armature coils from one pole of the field-magnets to another. Such machines are called alternating current machines.

With a suitably-constructed dynamo and an economical and reliable steam engine, an electric current can be generated cheaply without fear of failure.

III.—Distribution of Electricity.

We now understand the apparatus by which we obtain the electric light. The next question is how to supply a number of lamps from one engine room. I place a number of lamps in a long chain, so that the same electric current passes through all of them. This is what is called a series arrangement. It has a disadvantage. Suppose one of the lamps be broken, what happens? It breaks the electric circuit. I break one of these lamps placed in series, and all the others are extinguished; there is no longer a complete conducting circuit through which the current can flow. Mr. Edison has used another plan. He leads two wires from the two poles of the machine all over the district to form the main conductors, and wherever he has a lamp he leads two wires from it to the main conductors. A complete circuit is then offered for the current to pass along, and the lamp is luminous. Then I have Edison's parallel system. You see the main conductors to which ten lamps are attached in the way I have described. Now I break one of them, but the others are not affected. This plan is very simple to work, but it is not suitable for carrying the current to a distance, as I will presently explain.

When I was asked to choose a subject on which to lecture to you, I felt that I should best be discharging my duty if I chose that branch of practical and applied science to which I have devoted the most attention. This subject is the means of distributing electric current to a large district from a central station. In this case a thin wire does not suffice to carry the large current required for all the lamps. Such a wire would get very hot, and more steam power might be used in heating the main conductors than in causing the lamps to shine. It is easy to calculate what size of conductor would be the most economical. I have here two great rods, each a foot in diameter, and this is the size required to supply a district with 100,000 lamps in the most economical way if the conductors were made of the best material, which is pure copper. You can see at a glance that the cost of some miles of such conductors would be prohibitive.

The great difficulty of an engineering character which was encountered in the early attempts to introduce central station electric lighting lay in the enormous cost of the copper conductors required to carry the current. This, as much as the Electric Lighting Act of 1882, was the cause of the abandonment of all the earlier schemes.

If we do not lay down thick conductors we suffer in two ways. First, the electric pressure is used up in the mains to such an extent that different consumers along the route of the mains do not get the same electric pressure, and the pressure at each house varies with the amount of light being used in other houses.

Secondly, there is a great loss of energy in forcing the current through the thin mains. By thickening the mains we increase our capital expenditure, but we reduce the annual waste of energy in the mains, and it is easy for the engineer to determine the most economical arrangement.

On doing this it was found that the cost was prohibitory for supplying large districts. Deeply interested as engineers were in the progress of electric lighting, no engineer of eminence supported these early and crude schemes.

The plan originally proposed was to lay positive and negative mains all over the streets, and to connect the lamps singly or in groups to these mains by wires. This can only be done economically in small establishments where the greatest distance of a lamp from the machine along the route of the conductors is little more than 200 yards. It is excellent for clubs, hotels, and country houses.

If we connect each pair of our lamps in series, so that the same current passes through both, the electric pressure must be doubled but the current is halved, and at once we have a reduction in the size required for the mains. The disadvantage of this is that if one of the lamps of a pair goes out or is put out, the other lamp of the pair also goes out, as you see when I try the experiment. Here are twelve lamps arranged in six pairs, and when I extinguish one of a pair the other goes out. Now, if I connect together by another wire all the wires connecting the pairs, you will see that when I extinguish one lamp there is still a course open for the current, and no other lamp goes out. I extinguish three lamps of three pairs, and still no other lamp goes out. But you do notice that the three top lamps are fed by the same amount of current as the six bottom ones, and are so much brighter. This is a serious disadvantage, but can be remedied by leading the middle connecting wire, which I just now introduced, to the middle of the battery or other source of electric energy which I am using. Now you see there is no difference in the brightness of the light, however many I may extinguish. This way of using three wires introduces a considerable economy in conductors, and extends the distance to which we can work economically to a quarter of a mile, as has been found from numerous trials, especially in America. This is generally called the three-wire system. This, however, still leaves us a long distance from central station lighting on a large scale.

The idea of using high electric pressure in the mains commends itself because it cheapens our conductors. We have doubled our pressure by using the three-wire system. Can we advance farther in the same direction? If we use 2,000 volts pressure instead of 100 volts (the ordinary pressure of a glow lamp), we reduce the copper in our conductors about 20-fold. But it is impossible to permit 2,000 volts pressure in houses where people might get shocks and be killed. It has been proposed to charge 1,000 cells of a secondary battery in series from a central station, and discharge them to a small district 50 cells in series. This would involve a storehouse for every quarter of a square mile or even less. The system would be very good were it not for the expense of secondary or storage batteries. This puts the matter at present out of the question. It may come in time. It has the enormous advantage of leaving the system in working order even when machinery gives way, and of storing up an unusual amount of energy for special occasions, such as a general illumination. At present there is only one system thoroughly worked out for using high pressure in the mains and low pressure in the lamps. It is founded upon Faraday's discovery of induction. When I send an electric current through a coil of wire which has an iron core, the latter becomes a magnet, and continues to be one so long as the current is continued. During the act of magnetising, a certain amount of work is done, and is stored up in the magnet. At the moment when the current ceases, this energy is re-stored by the magnet in the form of additional current. Here I have an electro-magnet with two iron limbs separately wound. The wire of one limb can be connected with an incandescent lamp; that of the other with a battery. I now pass a current through the wire on one limb. Next I connect the glow lamp to the wire of the other limb. I now break the electric circuit, and you see that the glow lamp in the second circuit glows for a moment. The energy stored in the magnet is given up to the glow lamp.

An induction coil consists of an iron core surrounded by two coils, one of thick wire, the other some miles long but of very thin wire. It also has a means for rapidly interrupting the electric current from a battery in the short thick coil. This magnetises and demagnetises the iron core. The iron core gives off energy to the long thin coil, and an intermittent current of very high pressure is set up in that wire. You see that long sparks flash through the air from one end of the wire to the other. I now pass the current thus obtained through a resistance equivalent to many miles of telegraph wire, and send it through the thin coils of induction apparatus at the other end of the room. This magnetises and demagnetises the iron core, and if I connect the thick coils of the distant apparatus with glow lamps you see them shine brightly.

Here we have a high-pressure current which can be sent over a distance of many miles through a thin wire, and then converted into the ordinary low pressure required for lighting purposes. The system to be perfect must be worked by a dynamo machine which gives a high-pressure current of electricity alternating in direction. The first person to use such an alternating current of high tension in the mains and convert it by means of efficient apparatus into a current of the ordinary pressure required for the lamps in a house was M. Gaulard. It is now being largely used both in Europe and in America. An engineer has the greater confidence in recommending this system because, if ever storage batteries become available, the same system of conductors will do, and no change need be made.

IV.—Main Conductors.

I must now say a word about the main conductors. These may be laid either overhead or underground. The former plan has most generally been adopted in England and America. In America, because the prime cost is less; in England, because the Electric Lighting Act imposes prohibitive conditions on underground conductors, but does not deal with overhead ones. For a permanent works there is no doubt that underground conductors are the best, and also the cheapest in the end if the contractors are not mulcted for the concession.

It has been said that no good system of underground conductors exists. This is sheer nonsense. The plan I will explain is not by any means the only one, but I believe it to be the cheapest and perhaps the most complete. It has also the merit, as a system to describe, of novelty.

Gas pipes are laid down in the ordinary way to serve as a trough for the conductors. Gas pipes are used because sixty years' experience has taught us what they will do, and made our workmen acquainted with them, and they cost little. Two porcelain discs in each pipe serve as insulators. They are pierced with three holes (say an inch diameter) for the three-wire system, and with more or less holes in other systems according to requirements. Through these holes are passed thin split copper tubes, which by springing out grip the porcelain insulators. Into the ends of these, the ends of additional lengths of split tubing are squeezed. Thus we get a long length of gas piping, with two or three or more insulated copper tubes. These copper tubes are not the conductors, but serve other purposes.

Manholes with sumps are provided at every cross street. Naked wire is drawn through the copper tubes, only as much copper wire being used as suffices for immediate wants. Additional wire can be added as consumers are added to the district. When a house is to be joined to any part of the mains, a hole is tapped in the gas pipe and wires soldered on to the copper tubes, and enclosed in a small iron gas-tube screwed into the main pipe. The number of wires can at any time be added to or diminished. When the tube is two-thirds full, it is difficult to pull more wire through. The old wires may then be removed and a bare cable of wire filling the whole tube drawn through.

I believe that in speaking to practical working men, as I am just now, I am addressing those who can appreciate the benefits of this system, which I have not time to dwell on more fully at present.

V.—Meters.

The only weak part of a system which uses alternate currents with induction coils, is that till lately no meter existed which would measure the consumption of electricity. I am glad to be able to illustrate the principles of a meter which now acts equally well for alternate and continuous electric currents. Here I have a spiral cut out of a circle of paper. It is supported on a point at its middle. A coil of wire is below it, and an electric current passes through the coil and heats it. Thus a current of air is set up by convection, which turns the paper spiral as you see clearly when it is thrown on the screen. A more perfect vane has been made, which you can also see at work by the aid of the lantern. A train of wheels and pinions is attached for counting the number of revo-

make its way through three sets of turbines of increasing dimensions.

The lecture commenced with a description of the arrangements for the lighting of the theatre, and for raising and lowering the lights as required for stage effects. Three times the theatre was put into darkness as though an accident had happened to the machinery, and on each occasion one of the "panic circuits" was switched on either from the stage or the ticket office outside. One of these panic circuits contains an incandescent lamp of 1,000 candle-power constructed by Messrs. Clarke, Chapman, Parsons and Co., and it was surprising to notice how well the large building was lighted by this lamp alone. All the rest of the arrangements for the lighting of the theatre have been carried out by Messrs. J. H. Holmes and Co., of Newcastle, whose "panic circuit" is connected with the picture gallery lights quite independent of all the other lamps in the theatre. The account which we have given of the apparatus on the stage will convey to our readers a fair idea of what the rest of Prof. Garnett's lecture comprised. There was a full house, the audience consisting largely of working men. Arrangements have been made for scientific lectures every Monday and Saturday evening until the close of the Exhibition.

ELECTRIC LIGHTING FROM CENTRAL STATIONS.*

I.—Electric Lamps.

If I use a galvanic battery or a dynamo machine as a source of electricity, and connect its poles by a metal wire, an electric current flows through the wire. If I break the wire at any point, the current ceases to flow. If part of the wire be wound round a bar of iron, a noise is heard, and a bright momentary flash is seen at the instant of breaking the circuit. If the iron bar be U-shaped so as to form an electro-magnet of the usual type with poles, then by causing the rupture of the wire to take place between the poles I can increase enormously the noise and momentary character of the flash.

If, on the other hand, the wire be not coiled and has no iron near it, the act of breaking the wire does not give rise to noise, and the flash is not so instantaneous; in fact, the flash can be rendered permanent by holding the two broken ends at a short distance. I am now using a copper wire. I hold the ends at a distance of one-eighth of an inch, and you see a steady green light. I replace the copper by iron, and you see a redder colour. Again, if I use zinc the colour is blue. In each case the heat developed suffices to melt the metal and evaporate it, and the distinctive colour is given off only when the metal is in the form of vapour.

Carbon in the form of charcoal, however, does not melt or evaporate even at a very high temperature. When now I use two charcoal rods in the part of the circuit which I break, we have the brilliant white incandescence of a solid body at the highest attainable temperature. This is what is generally known as the arc light. It was discovered by Sir Humphry Davy at the beginning of the century. Since that time the ingenuity of inventors has led to the introduction of numerous devices for maintaining the distance of the carbons constant. One of the most successful of these inventions is the lamp of Messrs. Brockie and Pell, which I have here, and whose steady bright silent light must please the most critical eye. I throw an image of the carbon points on the screen. You notice that from the carbon connected with the positive pole of the battery particles fly off, and it becomes hollowed into a white crater of brilliant incandescence. On the negative carbon a pile of carbon is heaped up. Both carbons are meanwhile being consumed by the oxygen of the air. Hence a feeding action is required to maintain a constant distance between the points. This is regulated by a simple mechanism, and we have a practical lamp suitable for street lighting, and for the illumination of workshops and large halls or open spaces.

But it is not necessary to sever the metallic conductor in order to get intense heat and light. No substance is a perfect conductor, and the energy of the electric current is partly used up in heating the materials through which it passes. I pass the current through a platinum wire. It glows with intense heat. I increase the current, and the incandescence of the wire is white. I have chosen platinum because the temperature of melting is high, and it is not consumed by the oxygen of the atmosphere But even platinum has a melting temperature, and now when I increase the current still further it melts and the source of light has broken down.

The radiant energy of this wire consists partly of heat rays which are invisible to our eyes, and partly of visible rays. The higher the temperature the greater is the proportion of visible rays. Thus by choosing platinum with its high melting point we have chosen an economical source of light.

Carbon, however, has a higher melting point, and we can obtain fine threads or filaments of carbon. It must therefore be economical. Here I have such a filament exposed to the air. I pass a current through it. It gives a brilliant flash for a second, and is consumed by the oxygen of the atmosphere. Clearly we must remove this defect. I have a similar filament in a glass globe full of nitrogen gas, and now the filament shines as the current goes through it. Of course you would expect the heat to be used up by contact with the nitrogen gas setting up convection currents and cooling the filament. Let us see if this is the case. Here I have an exactly similar filament in a similar glass bulb from which all trace of air or gas has been, so far as possible, exhausted. I pass the same electric current through both. The one with nitrogen gas is dull, the one in vacuo shining with marvellous brilliancy.

This last is the incandescent lamp of the present day, whose mellow light is so pleasing to the eye. It is safe, cleanly, and healthy. Safe, because it cannot set fire to inflammable objects and cannot explode like gas; cleanly, because it has no noxious gases to tarnish silver and decorations; healthy, because it does not pollute the atmosphere, and does not heat it as gas does. Its safety has been shown by the action of the municipality of Paris, who, after the burning of the Opera Comique by gas, ordained that all theatres are to be lighted by these electric lights. Its good qualities are proved by the fact that every one who has the means furnishes his house with this light, and by the fact that the public are crying out at the action of Parliament in hindering the public supply of electricity by legislation in support of the gas monopoly.

You have now seen two methods by which electricity can be utilised for producing the electric light—the arc and the incandescent systems. I do not know of any other that is possible, except that perhaps in the future the brilliant discoveries of Mr. Crookes may be turned to practical account. That eminent investigator has discovered that if an electric current be passed through a glass tube or bulb nearly emptied of air, and if certain substances be placed in the glass bulb, they shine with a brilliant light. You are aware that some substances are said to be phosphorescent, which means that after having been exposed to a powerful light they shine in the dark. I have here six bottles, each containing a different fluorescent substance. I illuminate them for a few seconds by holding them before the light of burning magnesium, and now on darkening the room they give off a feeble light. Visionaries have been known who hoped that some day our houses will all be painted with some such substance, so that the solar energy stored up in the day may return to us a general illumination at night. In the meantime we know that by subjecting such substances to the electric current of great pressure which we get from the induction coil, they do, if enclosed in a nearly perfect vacuum, give off a light far more brilliant than the phosphorescence you have just seen. Through the kindness of Dr. De la Rue, I am able now to show you such brilliant effects, and you will observe that while I am using up the feeble amount of electrical energy supplied by this induction coil, I am producing an illumination which lights up all the objects in the neighbourhood.

We have, however, at present no practical application of these brilliant discoveries of Mr. Crookes.

II.—Generators of Electricity.

Having now glanced at the lamps at our disposal for utilising the electric current, viz., the arc lamp for streets and large halls, and the incandescent or glow lamp for interiors of dwelling houses, let us glance for a moment at the means which we have at our disposal for generating the electric current. There are in general use two ways of generating this kind of energy; the first by transforming chemical into electrical energy, the second by transforming the mechanical energy of water, steam, &c., into electrical energy. The loss in either case need not amount to more than 10 per cent. The apparatus which utilises chemical action is called a galvanic battery, or simply a battery. The best of these are secondary batteries in which, when the chemical energy is used up, it can be restored by charging with those machines which convert mechanical into electrical energy. We have several excellent secondary batteries, the best I know being that called the Union Battery. The Electric Power and Storage Company, and Elwell-Parker both supply a good secondary battery which has long stood the test of experience. Any one of these batteries has two terminals, to which the ends of an electric circuit can be attached, and then an electric current flows through the circuit. When the battery is exhausted, a current is sent through it in the reverse direction, and it is renovated.

All the machines at present used for converting mechanical into electric energy are founded on the discovery of Faraday that by moving about a coil of wire in the neighbourhood of a magnet, an electric current can be started in the coil. The same coil will experience a force tending to move it if an electric current flows through it while it is in the neighbourhood of a magnet. A machine constructed on this principle is usually called a dynamo machine, and it can be used either to convert mechanical into electric energy, or *vice versâ*. I will now show by the aid of the lantern a model of such a dynamo running as a motor when an electric current is passed through its coils.

I do not wish to waste your time by showing the details of dynamo machines. A dynamo contains generally four special parts:—(1) Pieces of iron with insulated wire coiled round them. These are called field-magnets, and are fixed in the framework of the machine or else form part of it. (2) Revolving coils of insulated wire. These form what is called the armature. (3) A commutator consisting of a number of bars of metal connected to the coils and revolving with them. (4) Two wire brushes fixed to the framework, rubbing against the commutator bars. To these last are attached the ends of the conducting circuit through which a current is to flow. Part of the electric energy is generally diverted through the wire coils on the field-magnets so as to magnetise them. The object of the commutator is to convert the electric current, which is reversed in the coils at each half rotation which they make, into a continuous current in the external circuit.

I now throw on the screen an end view of such a dynamo, and you will observe the field-magnets and brushes which are fixed. But by turning a handle you now see the central armature and the commutator on which the brushes rub rotating continuously. You can recognise these four parts in any of the ordinary dynamos. Sometimes, however, there is no object in having a continuous current in the external circuit, in which case the commutator is dispensed with, and the two ends of the wire coils in the armature are connected to two metal rings on and concentric with the spindle. The brushes rubbing on these lead to the external circuit a

* A lecture delivered by Prof. George Forbes, M.A., F.R.S., to working men at the Manchester Meeting of the British Association, September 3rd, 1887.

Digitized by Google

current which is reversed in direction at each passage of the armature coils from one pole of the field-magnets to another. Such machines are called alternating current machines.

With a suitably-constructed dynamo and an economical and reliable steam engine, an electric current can be generated cheaply without fear of failure.

III.—Distribution of Electricity.

We now understand the apparatus by which we obtain the electric light. The next question is how to supply a number of lamps from one engine room. I place a number of lamps in a long chain, so that the same electric current passes through all of them. This is what is called a series arrangement. It has a disadvantage. Suppose one of the lamps be broken, what happens? It breaks the electric circuit. I break one of these lamps placed in series, and all the others are extinguished; there is no longer a complete conducting circuit through which the current can flow. Mr. Edison has used another plan. He leads two wires from the two poles of the machine all over the district to form the main conductors, and wherever he has a lamp he leads two wires from it to the main conductors. A complete circuit is then offered for the current to pass along, and the lamp is luminous. Then I have Edison's parallel system. You see the main conductors to which ten lamps are attached in the way I have described. Now I break one of them, but the others are not affected. This plan is very simple to work, but it is not suitable for carrying the current to a distance, as I will presently explain.

When I was asked to choose a subject on which to lecture to you, I felt that I should best be discharging my duty if I chose that branch of practical and applied science to which I have devoted the most attention. This subject is the means of distributing electric current to a large district from a central station. In this case a thin wire does not suffice to carry the large current required for all the lamps. Such a wire would get very hot, and more steam power might be used in heating the main conductors than in causing the lamps to shine. It is easy to calculate what size of conductor would be the most economical. I have here two great rods, each a foot in diameter, and this is the size required to supply a district with 100,000 lamps in the most economical way if the conductors were made of the best material, which is pure copper. You can see at a glance that the cost of some miles of such conductors would be prohibitive.

The great difficulty of an engineering character which was encountered in the early attempts to introduce central station electric lighting lay in the enormous cost of the copper conductors required to carry the current. This, as much as the Electric Lighting Act of 1882, was the cause of the abandonment of all the earlier schemes.

If we do not lay down thick conductors we suffer in two ways. First, the electric pressure is used up in the mains to such an extent that different consumers along the route of the mains do not get the same electric pressure, and the pressure at each house varies with the amount of light being used in other houses.

Secondly, there is a great loss of energy in forcing the current through the thin mains. By thickening the mains we increase our capital expenditure, but we reduce the annual waste of energy in the mains, and it is easy for the engineer to determine the most economical arrangement.

On doing this it was found that the cost was prohibitory for supplying large districts. Deeply interested as engineers were in the progress of electric lighting, no engineer of eminence supported these early and crude schemes

The plan originally proposed was to lay positive and negative mains all over the streets, and to connect the lamps singly or in groups to these mains by wires. This can only be done economically in small establishments where the greatest distance of a lamp from the machine along the route of the conductors is little more than 200 yards. It is excellent for clubs, hotels, and country houses.

If we connect each pair of our lamps in series, so that the same current passes through both, the electric pressure must be doubled but the current is halved, and at once we have a reduction in the size required for the mains. The disadvantage of this is that if one of the lamps of a pair goes out or is put out, the other lamp of the pair also goes out, as you see when I try the experiment. Here are twelve lamps arranged in six pairs, and when I extinguish one of a pair the other goes out. Now, if I connect together by another wire all the wires connecting the pairs, you will see that when I extinguish one lamp there is still a course open for the current, and no other lamp goes out. I extinguish three lamps of three pairs, and still no other lamp goes out. But you do notice that the three top lamps are fed by the same amount of current as the six bottom ones, and are so much brighter. This is a serious disadvantage, but can be remedied by leading the middle connecting wire, which I just now introduced, to the middle of the battery or other source of electric energy which I am using. Now you see there is no difference in the brightness of the light, however many I may extinguish. This way of using three wires introduces a considerable economy in conductors, and extends the distance to which we can work economically to a quarter of a mile, as has been found from numerous trials, especially in America. This is generally called the three-wire system. This, however, still leaves us a long distance from central station lighting on a large scale.

The idea of using high electric pressure in the mains commends itself because it cheapens our conductors. We have doubled our pressure by using the three-wire system. Can we advance farther in the same direction? If we use 2,000 volts pressure instead of 100 volts (the ordinary pressure of a glow lamp), we reduce the copper in our conductors about 20-fold. But it is impossible to permit 2,000 volts pressure in houses where people might get shocks and be killed. It has been proposed to charge 1,000 cells of a secondary battery in series from a central station, and discharge them to a small district 50 cells in series. This would involve a storehouse for every quarter of a square mile or even less. The system would be very good were it not for the expense of secondary or storage batteries. This puts the matter at present out of the question. It may come in time. It has the enormous advantage of leaving the system in working order even when machinery gives way, and of storing up an unusual amount of energy for special occasions, such as a general illumination. At present there is only one system thoroughly worked out for using high pressure in the mains and low pressure in the lamps. It is founded upon Faraday's discovery of induction. When I send an electric current through a coil of wire which has an iron core, the latter becomes a magnet, and continues to be one so long as the current is continued. During the act of magnetising, a certain amount of work is done, and is stored up in the magnet. At the moment when the current ceases, this energy is re-stored by the magnet in the form of additional current. Here I have an electro-magnet with two iron limbs separately wound. The wire of one limb can be connected with an incandescent lamp; that of the other with a battery. I now pass a current through the wire on one limb. Next I connect the glow lamp to the wire of the other limb. I now break the electric circuit, and you see that the glow lamp in the second circuit glows for a moment. The energy stored in the magnet is given up to the glow lamp.

An induction coil consists of an iron core surrounded by two coils, one of thick wire, the other some miles long but of very thin wire. It also has a means for rapidly interrupting the electric current from a battery in the short thick coil. This magnetises and demagnetises the iron core. The iron core gives off energy to the long thin coil, and an intermittent current of very high pressure is set up in that wire. You see that long sparks flash through the air from one end of the wire to the other. I now pass the current thus obtained through a resistance equivalent to many miles of telegraph wire, and send it through the thin coils of induction apparatus at the other end of the room. This magnetises and demagnetises the iron core, and if I connect the thick coils of the distant apparatus with glow lamps you see them shine brightly.

Here we have a high-pressure current which can be sent over a distance of many miles through a thin wire, and then converted into the ordinary low pressure required for lighting purposes. The system to be perfect must be worked by a dynamo machine which gives a high-pressure current of electricity alternating in direction. The first person to use such an alternating current of high tension in the mains and convert it by means of efficient apparatus into a current of the ordinary pressure required for the lamps in a house was M. Gaulard. It is now being largely used both in Europe and in America. An engineer has the greater confidence in recommending this system because, if ever storage batteries become available, the same system of conductors will do, and no change need be made.

IV.—Main Conductors.

I must now say a word about the main conductors. These may be laid either overhead or underground. The former plan has most generally been adopted in England and America. In America, because the prime cost is less; in England, because the Electric Lighting Act imposes prohibitive conditions on underground conductors, but does not deal with overhead ones. For a permanent works there is no doubt that underground conductors are the best, and also the cheapest in the end if the contractors are not mulcted for the concession.

It has been said that no good system of underground conductors exists. This is sheer nonsense. The plan I will explain is not by any means the only one, but I believe it to be the cheapest and perhaps the most complete. It has also the merit, as a system to describe, of novelty.

Gas pipes are laid down in the ordinary way to serve as a trough for the conductors. Gas pipes are used because sixty years' experience has taught us what they will do, and made our workmen acquainted with them, and they cost little. Two porcelain discs in each pipe serve as insulators. They are pierced with three holes (say an inch diameter) for the three-wire system, and with more or less holes in other systems according to requirements. Through these holes are passed thin split copper tubes, which by springing out grip the porcelain insulators. Into the ends of these, the ends of additional lengths of split tubing are squeezed. Thus we get a long length of gas piping, with two or three or more insulated copper tubes. These copper tubes are not the conductors, but serve other purposes.

Manholes with sumps are provided at every cross street. Naked wire is drawn through the copper tubes, only as much copper wire being used as suffices for immediate wants. Additional wire can be added as consumers are added to the district. When a house is to be joined to any part of the mains, a hole is tapped in the gas pipe and wires soldered on to the copper tubes, and enclosed in a small iron gas-tube screwed into the main pipe. The number of wires can at any time be added to or diminished. When the tube is two-thirds full, it is difficult to pull more wire through. The old wires may then be removed and a bare cable of wire filling the whole tube drawn through.

I believe that in speaking to practical working men, as I am just now, I am addressing those who can appreciate the benefits of this system, which I have not time to dwell on more fully at present.

V.—Meters.

The only weak part of a system which uses alternate currents with induction coils, is that till lately no meter existed which would measure the consumption of electricity. I am glad to be able to illustrate the principles of a meter which now acts equally well for alternate and continuous electric currents. Here I have a spiral cut out of a circle of paper. It is supported on a point at its middle. A coil of wire is below it, and an electric current passes through the coil and heats it. Thus a current of air is set up by convection, which turns the paper spiral as you see clearly when it is thrown on the screen. A more perfect vane has been made, which you can also see at work by the aid of the lantern. A train of wheels and pinions is attached for counting the number of revo-

Digitized by Google

lutions of the vane, and this number is absolutely proportional to the quantity of electric current which has passed through the coil, whether rapidly or slowly.

VI.—Conclusion.

In conclusion, let me say a few words on the progress of central station electric lighting. In this country it has been slow, owing largely to the Electric Lighting Act of 1882. If electricity be put on the same terms as gas, and if you have your station on a river bank or any place where coal and water are cheap, you can be well supplied with electric light at the same price as gas at 3s. per thousand feet, with a fair profit to the undertakers. On the continent of Europe there are numerous central stations, mostly small, some supplying 30,000 lights. In America the progress has been enormous. Arc lights in series are used largely for street lighting and for shops, and central stations for glow lamps have been plentifully started on the parallel, three-wire, and induction systems. Most of the best companies concerned pay good dividends. The total money invested in electric lighting in the United States is estimated this year to amount to £30,000,000. In 1886 there were 58 Edison central stations supplying 149,900 lamps, besides 181,463 lamps in isolated plants. The Westinghouse Company has during this year been setting up central stations at the rate of 12,000 lamps per month. It is estimated that in 1885 the Brush Company alone had 96,000 arc lamps in use in the States, the number having doubled in each year from 1881. At present there are probably 300,000 arc lamps in use in that country.

The Americans are also getting the start of us in electric railways. We once beat the whole world in steam railways. Our pre-eminence in steam has gone far to make this country what it is. So let it be with electricity, for we are now passing into the Age of Electricity.

REPORT OF COMMITTEE ON ELECTRICAL DISTRIBUTION BY ALTERNATING CURRENTS.*

BY MR. SLATTERY.

One short year ago the commercial success of the branch of electric lighting in which induction coils are used was by some of our best authorities considered very problematical, but practical use of the induction system has not only succeeded in commercially converting high-tension electricity to low tension for electric lighting purposes, but also high-tension theoretical opponents by practical demonstration of facts.

Upon the occasion of the last Convention the extensive use of the induction system received its first authoritative endorsement by our esteemed friend, Dr. Otto Moses, and although he was by some considered over enthusiastic in his statements, time has served to prove the correctness of his views and the realisation of many of his anticipations.

We will go back six months, and mentally what do we see in this business from here? A few experimental plants scattered about in various parts of the country, struggling for public recognition and with the innumerable detail difficulties which dog the footsteps of every new departure, difficulties the magnitude of which are usually in proportion to our ignorance of their nature, and therefore more frequently than not unduly magnified.

Now what have these difficulties been, and has the past six months' experience enabled the manufacturing companies engaged in this branch of business to eliminate them? We find there were three factors in the induction system that required all the ability of the electrical engineer to work out and place upon a proper footing, namely the dynamo machine, the induction coil, and the disposition of the external circuit to take the best advantage of the use of the induction coil. Of course there were alternating dynamos in existence, as were also induction coils, before this lighting branch of business had acquired any prominence, but they were not such as would meet the new requirements.

We will first take the dynamo. It will be familiar to all of you that no matter how intimately acquainted you may be with the construction of a dynamo machine when you start to build a new type, your previous experience, however valuable it may be, does not enable you to foresee innumerable detailed difficulties which will assuredly develop with practical use, and which take time to ascertain and remedy.

Well, so far as we have been able to learn, the weaknesses which developed in this apparatus were, first, the liability of the current to jump across the coils in the event of the field being excited with the armature circuit open. This open circuit sometimes happened by a dead cross occurring at some place in the mains blowing the fuse at the dynamo, thus opening the circuit, and then the field being fully excited the armature would generate an exceedingly high electromotive force for an instant; the current under the circumstances would be very liable to jump across the coils of the armature, and other hurtful effects to the machine would ensue. The remedy for that was inserting at every branch in the external circuit a junction fuse, and at various points along the main and sub-mains section fuses to such an extent as to make an open main a remote contingency. It was also found that the armatures heated excessively, owing to the presence of the plaguy Foucault currents; it was found that this evil could be almost wholly suppressed by building the armature without iron, and avoiding as much as possible the use of masses of metal in proximity with the armature coils. In this connection Siemens' early type of alternating dynamo, slightly modified to meet the new requirements, might read us a lesson.

It was a bold step when the alternating dynamos were constructed with iron cores, and those who make this class of machine for this high-tension incandescent business might give us some interesting information. To my mind this iron core construction speaks of disagreeably high temperature. I do not say that they will not be able to present a rational theory why this evil may not be or has not been greatly modified; but the fact existed in the past, and as far as we have been able to ascertain stands unrefuted at present. One thing, however, is pretty evident, that just now this type of machine appears to be finding a rather extensive use, evidencing that it must be doing good work. So much for the alternating current dynamo, a machine destined to play a most important part in the future electric lighting business, and in the light of the past experience no doubt should exist in the minds of anyone here that these dynamos in practical use are now almost, if not quite, as reliable as any other dynamo, while coupled with this is the important factor of a pretty close self-regulating property attainable in this system, without the necessity for any particular method of winding—that property, following chiefly as the result of the use of the induction coils. It is satisfactory to know that during the probation of this system every accident of any importance which has occurred to the dynamos has been of a purely mechanical nature, and our mechanics have reduced them to a minimum.

No doubt the induction coils have been a source of considerable anxiety, not because there was any obstacle in the way of obtaining high electrical efficiency, this latter appears not to have been by any means a difficult problem to solve; the source of greatest trouble has been, as far as I can learn, that of insulation. In what form will the weakness appear? has been the question often asked himself by a timid electrician, and as usual the most unlooked-for troubles developed. At one time an unaccountable defect in the insulation of the secondary coil would occur, cutting out a number of convolutions, thereby causing annoyance by reducing the incandescence of the lamps in its circuit. The remedy was simple—increase the insulation of the wire and exercise still greater care. The same accident would still more frequently happen to the primary coil; the same remedy applied overcame it. Sometimes a number of the layers of the primary coil would thus be suddenly cut out, resulting in the passage of a much heavier current than the fuse in the coil box had carrying capacity for; the fuse would then melt and possibly draw an arc that you had a great deal rather do without if you could. The remedy for that was, keep on insulating the primary coil layers from each other until the trouble ceased, and increase the distance between the ends of the primary fuse to such an extent that when the latter melted, an arc, no matter how great its volume, would not be able to bridge over the distance, which after all was calculable because the E.M.F. was constant. Then, again, metallic contact would take place between the induction coil and the iron box in which it was mounted, and if that box happened to be placed anywhere near a ground, possibly unpleasant electrical experiences might be related in wet weather. It was again only a question of looking out for the insulation to reduce such defects to a minimum. The insulation appears to have been looked out for, as the smooth and safe working of that branch of the business would now seem to testify, and to-day that part of the system can be made as reliable, simple and as easily disposed of as any other part of an incandescent system.

Thus the two new and troublesome factors have gradually and surely been strengthened for their future work.

The next in the system, viz., that method of distribution which would enable you to utilise the induction coil to the best advantage, although apparently presenting the simplest problems at the outset, has required a great deal more thought than was anticipated. It was found that no particular rule, as in the case of low-tension distribution, could be carried out, the methods of distribution varying with the condition of the district in which you had to distribute.

In some cases the wires were run out from the central station through the centre of distribution, and tapped at any point along the route where lights were required. This was the earliest and simplest form of distribution, and answers perfectly well for comparatively small installations, it being desirable to keep the loss in the mains down to about 2 per cent. and perhaps about 2 to 3 per cent. in the induction coils, so that the incandescence of the lamps should not vary appreciably throughout the system. This arrangement of the circuit may be carried out in small and very scattered towns, where it has been found to answer admirably. In other cases, where the district is more densely populated and a large installation is required, the inductoriums are placed in the centres of distribution and used like so many stationary dynamos, the light tension primary current with comparatively small conductors feeding each of these centres, the secondary or distributing circuit being taken where lights are required. Still, other methods of distribution are carried out, but what has been stated in this connection will serve to show that again the past year's familiarity with the business has given an opportunity to perceive and profit by many advantages the system offers.

One of the last but by no means the least points that I shall touch upon in this interesting subject is the question of comparative cost of the main conductors required in an installation of an induction and low-tension incandescent plant. Not at all unfrequently we shall find ourselves called upon to figure upon a plant like this.

From the source of generation to the point of distribution is one mile and a half, making a three-mile circuit; at the point of distribution you are required to distribute some 400 16 candle-power lamps at, say, 5 per cent. fall of potential, which appears to be about the limit allowed the induction system. The necessary conductors for this purpose in the induction systems now in use would be No. 2 Brown and Sharp, which will cost about $250. In the case of the installations upon the low-tension system you would require a conductor costing about $1,050.

Should you be required to distribute throughout the whole of the length of the circuit, the wire such as is used for ordinary arc lighting purposes would be amply sufficient for the induction, and of course a proportional reduction may be made in the low tension.

Now, a great many exaggerated statements are made with regard to the

* Paper read before the American National Electric Light Association.

Digitized by Google

dangerous shocks to be expected from this alternating current, and while I am not prepared to say that the physiological experience of a shock from a thousand-volt dynamo is the most agreeable thing in the world, I am prepared to say that the shock is by no means so severe as that received from a continuous current dynamo of the same voltage. A few weeks ago a man showed me his hands, which were horribly burned. He had received a shock from an eleven hundred-volt dynamo, and he said, with a visible tremor in his arms as if the recollection of that shock was still vividly impressed upon his mind, that he experienced the effect of that shock for more than a week afterwards. A friend of mine was testing a 400-light 1,050-volt alternating dynamo, fully loaded, only a few days ago, and going towards the machine his foot slipped and he fell quite close to it; in his confusion he quickly reached out his hands and unfortunately placed them directly upon the poles of the dynamo. He said from where he fell to the walls behind him was about fifteen feet, and it seemed to him as if that dynamo was suddenly converted into an electrical gun, and he got shot across the room until the velocity of his movement was interfered with by the wall. There was scarcely the appearance of a burn on his hands, merely a pin's head matter, while the effect of the shock was felt by him only for a few hours. It might be said that the difference of the effect of the shock was owing to the difference in the temperament of the two men; that may be so, but I have received three pretty severe shocks from a 1,000-volt alternating machine, and, however much I may have felt inclined to dispense with the shaking up it gave me, the experience was of value to me—one cannot have everything.

One word more in conclusion. The induction system has evidently come to stay, not because enthusiastic advocates think or say so, but because the expert public, the central station public, have practically endorsed it, because it more nearly than anything else meets their immediate, and anticipates many of their future, requirements. More especially is its advent doubly welcomed just now with this misconducted overhead conductor warfare pressing on every side, and which is every day acquiring seriousness in proportion to the increase of copper wire in the air, and I think that this system with its comparatively small mass of conductors, will postpone for a considerable time the necessity of going underground with the electric light wires until more extended experiments shall have given us the confidence in underground systems that experience in the past has materially shaken.

Mr. SMITH, of Alleghany City: Mr. Chairman—I would say that I have had some experience with the alternating system with which Mr. Duncan is connected, and also with another company in Philadelphia, where we started with the direct system first and then changed it to the alternating. There are some points on which Mr. Slattery has asked questions, and I think that on some of them I may be able to assist him. We have found that when you are using a converter system, it enables you to employ almost any system of distribution you want. In Pittsburg, where we were running lights in a rather poor neighbourhood, we found it cheaper to run secondary mains, attaching our lights in the houses from the secondary current, using fifty or one hundred volts as we pleased. In other parts of the town, where they were using fifteen or twenty lights in each house, we found it better to carry the converters into the building, or fasten them as close as possible on the outside wall, so as to enable us to use the fifty-volt lamps exclusively. In the case of hotels we would run a high-pressure wire down the centre of the corridor, and place converters at each group. In Philadelphia, where we had a direct current, and wanted to change to an alternating current, we changed without the slightest trouble three or four hundred lights from one system to the other without shutting off the light for a moment. Whenever we wished to change a section we would cut the section at that point, put in converters, and then splice up again.

In regard to the question of heating up the machines that Mr. Slattery speaks of, I would say that on the newer machines we run them for a week, starting them Sunday afternoon and stopping them Sunday morning. During all that time the machine never gets so hot that you cannot bear your hand on it, a fact which shows that the working of the machine is not very much interfered with. In the larger machines—the 1,300-light machines—we have one there that has been running about two months, stopping only about ten minutes per day, and if the engineer does not feel disposed to, he does not stop it then. We never had the slightest trouble in the way of heating. You can always bear your hand on it.

The converters I know absolutely nothing about. I put them in and that is the end of it. I think we have had to take out two during four months.

Mr. W. R. KIMBALL, of Boston: In regard to the alternating system for supplying incandescent lights, there has been a marked advance since the last Convention in Philadelphia. From the various installations which are at present in operation we have been able to get data which are not only interesting but useful. The question of the insulation of high potential wires is one which appeals to every part of the electric light station, whether he be line man or manager. In the one case it is his own life and limb that are involved, and in the other case it is property. And yet there is danger in carrying high-potential wires into cellars and basements.

There are very many cases where it is convenient and economical, in cities where we are not allowed to put the wires on poles, instead of putting the converter high up on a fixture—it is very inconvenient to put a converter of one hundred lights on the top of a man's building—to carry a *o* or *oo* wire down into the building, if a way can be devised to carry safely the currents which approach at least the intensity of arc currents into cellars and basements, and handle the apparatus without that sense of danger which is now felt. That is a thing that is needed at present.

The question of the insulation between the primary and the secondary of the inductive coil is governed by a variety of causes. Where converters are placed out of doors moisture will get in. No matter how carefully the wires may be placed the current will be affected. This bold expedient of grounding the inside wire has been brought to the attention of this Convention and the public by some of the electrical papers. It seems to me that it opens a field for discussion. The question naturally arises in the minds of insurance men whether running electrical wires down to the ground is not an unheard of thing. The fact must be considered that there is a plan for the complete isolation of this wire from any other wire in the town or city. It is not to be compared with the grounding of a positive wire in a system of distribution where seventy-five or one hundred volts are distributed.

In regard to distribution over a large area, in discussing incandescent lights, it seems to me that those of us who have the practical work to do are apt to lose sight of the fact that all the laws of wiring and construction work which apply to the low-tension wiring are equally applicable to the alternating system, and all the appliances made for straight incandescent work may be utilised for the alternating current by conforming to the laws now so well known regarding self-induction. And it is a question to be decided by the electric light engineers in practice to determine whether it is better to rely on the high-potential wires for a system of distribution and lay them with as much care as the low-potential systems, and place converters as near the lamps as possible, anywhere they may be required, or whether it is better to run a plainer system of high-potential mains and rely on inside wiring. By inside wiring I mean this: In many plants the converters are placed in groups connected by a main trunk secondary, which is practically the same as the mains in a system of distribution, so that part of the advantages of an alternating system are lost.

Mr. SMITH, of Alleghany City: I do not represent the Westinghouse people, but I have had exceptional opportunities for examining their work. In Philadelphia we are using their work. We have satisfied ourselves that if we can get a good metallic covering it is about as good as anything that is to be had. The outside covering of the cable was not insulated in any way from the iron junction box, though the wire carrying out current was. In some parts of the streets we found it difficult to lay the wooden boxes, and we used iron pipes through which we pulled the cables and filled the pipes with pitch to prevent the average Irishman from driving his pick through them. We have not had the slightest trouble from loss of current or anything else, and our men handle those cables with perfect impunity. I understood that some experiments had been made by the Westinghouse Company with regard to insulation. I made some inquiries of them, and their answer was that we could use any kind of cable that we wanted as long as the covering was good; but for practical reasons they should recommend to us in this particular instance a lead covered cable, having both conductors in one lead covering. That is to say, two separate cables soldered together through their whole length. They made the test for me. They tested a quantity of cable thoroughly, and they told me that I would get perfect satisfaction out of it. The question was raised as to whether our men would not be liable to get shocks from the covering of the converters if they were not grounded. We tried it and found no effect whatever. I have had no experience with a long conduit of iron. Ours have always been short. It seems to me that any effect of the positive would be neutralised by the negative at any one instant.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the weeks ended 9th, 16th, and 23rd inst. amounted to £3,057, £2,477, and £2,873 respectively.

EASTERN TELEGRAPH COMPANY.—This company announce the payment on the 14th October next of a dividend of 3s. per share on the preference shares of the company, less income-tax, for the quarter ending 30th September, and an interim dividend of 2s. 6d. per share on the ordinary shares of the company, free of income-tax, in respect of profits for the quarter ended 30th June. The register of transfers will be closed from the 7th to 14th October, both days inclusive.

EASTERN EXTENSION TELEGRAPH COMPANY.—This company gives notice that the accounts for the half-year ended 30th June last show, subject to audit, a balance of profit of £66,655, after the payment of the interim dividend for the first quarter. The directors, on 28th inst., declared a dividend for the quarter ended 30th June of 2s. 6d. per share, free of income-tax, payable on October 15, and decided to carry the balance of £35,405 forward to the next account.

NEW TELEPHONE COMPANY.—According to a circular which has been forwarded to us, this company has completed new arrangements for manufacturing, and states that it is supplying an instrument of an entirey new design. The address of the company is 4, Great Winchester-street, E.C.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the three weeks ended September 23rd, were £2,406, £1,373, and £1,578 respectively, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

PERSONAL.—It has already been announced that Mr. Trotter, late partner in the firm of Goolden and Trotter, has left that firm. The partnership, we believe, has been dissolved by mutual consent, and Mr. Trotter will shortly return to London and be practically engaged in some branch of engineering. The existing business will be carried on by Mr. Goolden, under the title of W. T. Goolden and Co., and the firm will continue to work Mr. Trotter's patents, and conduct the factory which has hitherto been under his management. We have it on the best authority that Mr. Trotter wishes the firm all future prosperity. There is no doubt that the present position of the firm owes a

Digitized by Google

good deal to the energy and the ability of Mr. Trotter. He has designed and constructed dynamos and other apparatus which have commanded a considerable amount of business success, and there is no reason why, under the future management, they should not continue to do so.

BANKRUPTCY.—Oswald Ricketts Swete, of 108, Barons Court-road, West Kensington, and Albion Works, 141, Kensal-road, Westbourne Park, and 11, Victoria-street, London, lately trading in co-partnership with William Charles Main, as electric light contractors and engineers, under the firm of Swete and Main. The first meeting of creditors will be held on the 4th of October at 11 o'clock. It may perhaps be interesting to add one of the observations upon this bankruptcy. The debtor states that he began business in October, 1885, with borrowed money, £300 (included in unsecured creditors), and in March, 1886, took into partnership Mr. Wm. Chas. Main, who introduced £330 capital; that such partnership was dissolved in March, 1887, Mr. Main retiring and the debtor taking over the liabilities and assets of the firm, and agreeing also to pay a sum of £436 by instalments, of which a balance of £432. 8s. 6d. remains due. This partner is included among the unsecured creditors, but his claim appears to be one that must be postponed until the remaining debts are satisfied.

New Telephone Company,

LIMITED.

Under License from the Postmaster-General.

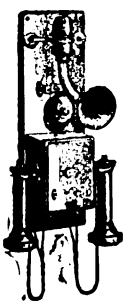
NOTICE.

This Company is now supplying an

ENTIRELY NEW TYPE OF INSTRUMENT,

distinct and clear in articulation, thoroughly efficient for long or short distances, easily fixed and maintained, and capable of perfect adjustment. The instruments now being issued may be relied upon as

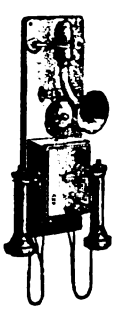
THE BEST AND CHEAPEST IN THE MARKET.



These Telephones are being SOLD to the Public OUTRIGHT. They are manufactured under the patents of Professor Silvanus P. Thompson and others, and are now in successful operation in leading towns in the kingdom.

Numerous Testimonials have been received from the Company's customers during the past three years, testifying to the satisfactory working of the Telephones supplied.

Instruments of the latest type, including Transmitter, Two Receivers, Call Bell, and Switch complete for each Station, at £6.



The Company will give a formal Guarantee to any purchaser requiring the same against any claims which may be made by trade rivals for alleged infringement.

Price Lists, Estimates, and Copies of Testimonials free on application to the SECRETARY,

New Telephone Company, Limited, 4, Great Winchester Street, LONDON, E.C.

Sole Agents for Sheffield, Leeds, Bradford, Halifax, Huddersfield, Derby, and Nottingham, Messrs. TASKER, SONS & CO., Sheffield.

NOTES.

FOREMAN OF TELEGRAPH WORKS REQUIRED.—The attention of those interested is directed to an advertisement by the Government of the Gold Coast to the above effect which will be found in another column.

BRIGHTON.—It is expected that telephone communication between Brighton and Lewes will be opened early next month. The difficulties of finding a route between Lewes and Eastbourne have now been surmounted, and this additional length of wire will soon be ready for use.

"WHAT IS ELECTRICITY?"—In another column will be found an interesting letter under the above heading from Mr. Townsend Wolcott. The original paper referred to will be found in our issue of July 15th, and our remarks thereon were given amongst the "Notes" of the same date.

THE LIGHTING OF THE CITY OF LONDON.—At the meeting of the Commissioners of Sewers, held on Tuesday last, Mr. J. C. Bell, in reply to Mr. Morris, said that he had no objection to state that, on the report of the engineer, Mr. W. Haywood, C.E., the Streets Committee intended to proceed with the lighting of Queen Victoria-street and Cannon-street by the electric light.

INSUFFICIENT TELEGRAPH ACCOMMODATION IN THE METROPOLITAN AREA.—The inhabitants of Plumstead consider that they have good ground for complaint in the fact that with a population of 40,000 there is only one telegraph office in the whole district. The inhabitants of New Eltham are, however, in a worse case. Here there is a population of over 10,000 without any telegraph accommodation whatever.

BANK OF ENGLAND.—We understand that the Bank of England have determined to put down two additional dynamos and a new engine for the purpose of lighting most of the remaining rooms and courts. The installation is being carried out under the supervision of Messrs. Drake and Gorham, and is, we understand, to be ready for running within the next two months. The installation at the Bank of England is one of the earliest in which accumulators were employed with continuous success.

THE "WATT" DYNAMO.—Our readers will have observed that a paragraph has been going the rounds of the daily press describing a new type of dynamo machine "invented by Mr. Hugh Watt, M.P.," of the Maxim-Weston Electric Lighting Company. We shall defer a description of this interesting machine, at least for the time being, but we must not omit to mention, on the authority of one of the paragraphs in circulation, that "it works at 1,000 revolutions per minute, is driven by a 14 horse-power engine, and gives 130 *ampere hours* (!) at 65 volts."

ELECTRIC LIGHT IN THE GERMAN ARMY.—A daily paper states that the German artillery has recently been carrying on a series of successful experiments in lighting forts with electricity, with a view to facilitate a bombardment at night. On the practising grounds, near Jüterbog, 36 guns of all calibres recently fired off 2,500 shrapnels and other missiles under the electric light, the distance being from 2,800 to 3,800 metres. The experiments took place in the presence of about 80 officers, including six generals. Though the night was very dark, the effect of every ball could be clearly seen.

PROTECTION OF LIGHTNING CONDUCTORS.—The *Illustrirte Zeitung für Blechindustrie* recommends the following method of protecting the copper wires of lightning conductors on factory chimneys from being affected by gases. The wires exposed should be provided with an insulating covering of india rubber, over which a protective composition should be applied of the thickness of 2-5ths of an inch. The latter is prepared by mixing ground fire-brick with finely chopped straw and clay-water into a moderate thick paste. After the composition has dried, asbestos string should be wound round it so as to prevent its crumbling away.

EDINBURGH.—Some curiosity was excited in Edinburgh on Saturday evening last by the appearance of a light of unusual character which moved slowly to and fro at a great height above Castle Hill. The explanation of the matter was that an experiment was being made with a captive balloon above the Observatory. Half-a-dozen incandescent lamps of twenty candle-power, each protected by a wire cage, were placed in the interior of the balloon, and were connected with the dynamo in the building below by means of two insulated wires. The effect was rather spoiled by a mist which hung over the city at the time. Experiments were also made in signalling by the Morse system.

THE WEST AFRICAN TELEGRAPH COMPANY.—The staff of the West African Telegraph Company (Limited) addressed the following message from São Thomé to Her Majesty upon the occasion of her Jubilee, June 20th:—"Your Majesty's most loyal subjects, the employés of the West African Telegraph Company, resident on the West Coast of Africa, desire your Most Excellent Majesty's happiness on this Jubilee day, and health and strength to long continue your Majesty's prosperous reign." The following reply was received:—"London, 22nd, 12:10 p.m. Employés, West African Telegraph Company: Queen thanks you and your comrades for loyal congratulations. —Private Secretary."

THE TELEPHONE IN CHINA.—Mr. Morgan, of the American Bell Telephone Company, contradicts the absurd rumour that proceedings had been taken to prevent the introduction of the Bell telephone in China. What has been done is merely in view of taking steps to prevent the manufacture of the instruments in America by unauthorised persons on behalf of the Philadelphia syndicate. It is obvious that unless the promoters of the new scheme have possession of an instrument beyond the scope of the Bell patent they must either purchase their instruments of one of the Bell companies, or they will have to manufacture in China or elsewhere, beyond the limits of the patent.

THE USE OF THE MAGNET IN THE MANUFACTURE OF PAPER.—During the manufacture of paper, as soon as the pulping machines exhibit signs of wear it is not uncommon for a good deal of paper to be spoilt by the abrasion of minute specks of iron which fall into the pulp and afterwards produce rust stains. Occasionally the stains do not appear until the paper has been damped for printing, and a good deal of annoyance is thus caused. The *Papier Zeitung* announces that this difficulty may be overcome by the use of magnets in a very simple and effectual manner. A kind of steel comb with broad teeth set edgewise is placed in the stream of pulp and water which issues from the machine. The teeth are made of magnetised steel strips, and any iron particles contained in the pulp are thus withdrawn.

THE FRENCH TELEGRAPHS AND THE RECENT MOBILISATION.—Our contemporary, *Electricité*, has some rather disparaging remarks concerning the use made of the telegraph during the recent mobilisation of a French army corps. The

Digitized by Google

telegraphists upon whom would devolve such important duties on the outbreak of war were not, in the opinion of our contemporary, sufficiently put to the proof during the mobilisation; the authorities were too easily contented to rely upon lines which already existed between the chief places in the district. Only one special line was put up; this extended from the railway at Carcassonne to the waggon depot at Estagnal. Communication with Paris was maintained by means of two lines from Castelnaudary, upon which Hughes's type-writers were employed, and the only measure of additional precaution it was deemed necessary to take appears to have consisted in the despatch of one spare instrument to Castelnaudary.

THE TELEPHONE IN AUSTRIA.—Austria is at the present time decidedly behindhand in the matter of telephonic communication. There are only 12 exchanges with 3,000 subscribers, of which 1,000 are in Vienna. The tariffs are very moderate. At Vienna the subscription amounts to 300fr. per annum up to a distance of two kilometres from the central exchange, with an addition of 60fr. per kilometre beyond this distance. At Brünn, Prague, and Trieste the charge is only 180fr. within a radius of two kilometres, and in the remaining towns it varies from 120 to 160fr. per annum, with an additional 40fr. per kilometre beyond the first two kilometres. The Austrian Government has recently opened an exchange of their own at Reichvau, a manufacturing town in Bohemia, and it is said that the results have been so satisfactory that they are now preparing to introduce the service in several other towns, amongst which are named Salzbourg, Cracow, and Klagenfart.

THE OLD STUDENTS' ASSOCIATION OF FINSBURY TECHNICAL COLLEGE.—The third annual dinner of the City and Guilds of London Finsbury Technical College Old Students' Association, was held at the Holborn Restaurant, on Friday, 29th ult. The chair was taken at seven o'clock by the president, Mr. Alfred Chatterton, B.Sc. Among the numerous guests were Profs. Ayrton and Armstrong, of the Central Institution, Profs. Thompson and Perry, of the Finsbury Technical College, Messrs. Blaine, M.E., Millis, J. H. Chatterton, and others. After dinner the principal toasts were "The College," proposed by the chairman and responded to by Prof. Silvanus Thompson; the "Central Institution," proposed by Mr. H. N. Lawrence and responded to by Prof. Ayrton; and the "Old Students' Association," proposed by Prof. Perry and responded to by the chairman as president of the association, and Mr. W. F. Pettigrew, as president-elect. With the above speakers, and an agreeable selection of music, an extremely interesting and enjoyable evening was spent.

THE LIGHTING OF THE OLYMPIA HALL.—We are informed that an addition is to be made to the number of arc lamps in the Olympia Hall at Kensington, in view of the return of the Paris Hippodrome in a few weeks' time. At present the electric light plant consists of some 60 Brush arc lamps and about 350 incandescent lamps. These are to be supplemented by 64 arcs, taking 10 amperes each. It appears that an immense quantity of light is required in the ring, as there are, in addition to the electric light, 10 large gas coronas, giving about 2,000 candle-power each, arranged in two rows over the arena. There is ample dynamo and engine power for the new lamps, which will be connected in parallel circuit, and arranged so as to be, in common with all the rest of the lighting, interchangeable on any of the machines. The work will be carried out by Mr. Arthur Carey, engineer to the Hall Company. The services of Mr. Guy C. Fricker, who has lately commenced practice as a consulting electrical engineer, are also engaged on the work.

THE BONTA (SO-CALLED) MAKE-AND-BREAK TELEPHONE TRANSMITTER.—In our issue of September 2nd we described a telephone transmitter recently brought out in America, in which a carbon ball rests against a carbon point, and is capable of a to-and-fro motion. By the aid of photography it was claimed to have been demonstrated that during the process of transmitting speech the ball was at times separated from the carbon point by a clear space, and on the strength of this demonstration it has been claimed that the instrument does not produce an undulatory current, and is thus clear of existing patents. We pointed out at the time that the conclusion set forth is not justified by the premises, unless it is also shown that the circuit is entirely devoid of self-induction. But, further than this, Mr. W. C. Barney, writing to a contemporary, now describes some observations of his own made upon this instrument, which is now being publicly exhibited in New York. He states that the receiver employed was an ordinary Bell, and that while the transmission was perfect while speaking in a low tone of voice, yet if louder tones were employed the instrument became absolutely dumb. From this it is perfectly clear that as soon as the degree of make-and-break exceeds the interval corresponding to the time constant of the circuit—that is, as soon as the current ceases to be undulatory—articulate speech ceases to be transmitted. It would be difficult to devise a better proof of the practical necessity of undulatory currents.

THE SUCCESS OF UNDERGROUND CONDUITS AT CHICAGO. Prof. J. B. Barrett, electrician to the City of Chicago, is justly entitled to the credit of having been the first to grapple successfully upon the large scale with the problem of underground conduits for electric wires of all descriptions. In a recent paper with the alluring title "How to Obviate the Danger Emanating from Overhead Electric Wires," Prof. Barrett said:—"We hear every day from somebody, away off down in some swamp or back alley, shouting at the top of his voice, 'Underground is a failure; it don't work!' And yet all the time it is working in Chicago; and in our conduits we have as many varieties of wires as there are above ground in any two cities of the Union—as many kinds, understand. We have everything, from a cable less than an inch in diameter, with fifty wires in it, up to a cable as big as your thumb, and only one wire in it; we have telegraph and fire alarm, and telephone and call bells, watch service, mercurial and burglar alarms, and police and—well, if you can think of anything else, call the turn; we've got it in our conduits, and they all work, and work far more satisfactorily than the overhead undertaker lines. Do not let the croakers rule you off the track." This is, of course, very satisfactory, but it must always be remembered that the overhead wire problem in the American cities is a very different thing from what we are accustomed to in this country. Instead of having to deal merely with telegraph and telephone wires, the American citizens are confronted at every turn with heavy cables conveying high tension arc lighting currents, or consisting of bundles of 50 or 100 telephone wires.

METHOD OF OBSERVING THE ACTION OF MAGNETS ON LIQUIDS.—Mr. S. T. Morehead, writing in Silliman's *American Journal* for September, describes a novel method of observing the action of magnets on liquids. He says:—"Some weeks ago one of my students, Mr. J. C. Child, and myself were working with a diamagnetic instrument, simply repeating well-known experiments. Plücker's method of observing the diamagnetism of liquids having failed in our hands to give satis-

Digitized by Google

factory results, we hit upon a method which was new to us and which was very satisfactory. Into a glass tube of about four or five millimetres internal diameter a small quantity of liquid was introduced forming a short cylinder. This tube was placed horizontally at right angles to the line joining the poles of the magnet, with the liquid nearly between the poles. When the current was turned on, the liquid was very evidently repelled. Water was repelled through a distance of about half a centimetre; wood spirit through a greater distance. By moving the tube in the direction of its length the wood spirit could be pushed any distance through the tube. The amount of motion is of course a function of the resistances due to adhesion and friction as well as of the repulsive force. The attraction of liquids is easily shown by the same method. A single modification of the above plan of proceeding is to incline the tube slightly so as to make the liquid flow toward the poles. If the acquired velocity be not too great the magnet acts as a break to stop the motion. It is well to bend the tube up a little at each end to prevent the liquids from flowing out. This method is well adapted for projection so as to be seen by large audiences."

Secondary Batteries at Brooklyn in 1871.—A few weeks ago Captain Henry Oceanus Cook met with a fatal accident by being run over and killed upon a railway near New York. The name of this remarkable man has not hitherto been familiar to ourselves, but if the following account, which appeared in one of the New York daily journals, contains any element of truth it would be interesting and even important to learn something more of his achievements. The journal in question, plunging at once *in medias res*, says:—"In 1864 he resigned his commission as Lieutenant-Commander in the Indian Navy and came to the United States, where he has ever since resided. At Portland, Me., he established a manufactory of electric appliances. He there constructed the first electric marine engine, and applied it to the propelling of a boat. But he had hardly become well established here when the great fire of 1866 destroyed every vestige of his work. He then established a factory at Boston. Here he designed and invented a trans-isthmian marine railway, and also a bicycle, but his applications for patents were rejected. He also invented a neutral marine compass, and his success was promising, when fire, in 1868, again destroyed his factory. The next year Capt. Cook came to New York. He invented an electric storage battery in 1871, and successfully applied it to the running of a street car in Brooklyn. In 1872 he invented a pocket electric lamp. He is said to have discovered processes by which alcohol was deprived of intoxicating properties and hydro-carbons made perfectly neutral. He also invented a 'broken line' telephone, which, however, had not reached perfection when he was killed. Since 1872 he has been continuously engaged in experiment and investigations in electric machinery and motors."

A Confession.—An American journal relates the following mournful tale:—"Johnny Norton, who a few years ago was well known all over the country as Bunnell's 'electric boy,' is now working in this city as a compositor. In reply to the query of a reporter as to what had become of his electricity he said: 'When I was on exhibition I was enclosed in an oblong stall about seven or eight feet long, the front of which was like a narrow counter. Opposite the counter was a rail which only allowed the visitors to pass in single file. A long strip of cocoa matting served as a carpet for the passageway, and also as a cover for a sheet of zinc which extended beneath it, running the length of the stall. My box was similarly invested with zinc and matting. Attached to the sheets of metal, but hidden from view, were the two poles of a galvanic battery, one under my feet and the other in the passage. Now, anyone passing over the zinc and touching me, behind the counter, completed the circuit and received a shock. So did I. The matting, of course, had to be kept damp, water being the conductor. It was surprising what intelligent people were duped by this trick. Why, I was kept shaking hands and being fingered from morning until night. Many is the $2 note I received from doctors and others for a couple of drops of my blood for analysis. One evening three or four young students came in to unmask me. One of them made a wager that he would electrify the audience the same way if he was in the box. I immediately invited him in and he accepted the challenge. I then retired, but before doing so I pressed a hidden button that cut off my wire. He, of course, failed, and ignominiously retreated, after being guyed unmercifully by those present. This proved me genuine to the satisfaction of every one in that town, and I became famous. There was a lot of fun in the business; but I had to give it up, as the constant strain caused by the battery was too much for me."

Electric Compared with Gas Illumination in Works and Factories.—On the *audi alteram partem* principle we reproduce the following letter, which Mr. H. Leicester Greville has addressed to our contemporary, the *Journal of Gas Lighting*:—"Sir: I read with very great interest the report of Prof. Fleming's able lecture on the above subject which appeared in last week's *Journal* (Sept. 20). The paper is strictly what its title would lead us to suppose—viz., a comparison between gas and electricity as sources of light in works and factories; and whilst not being blind to the advantages of electricity over gas in particular instances, I consider Prof. Fleming's paper scarcely does justice to gas on two particular points. Firstly, stress is laid in one or two instances on the improvement in the condition of the air of workshops consequent on abandoning the use of gas and adopting the electric light. The comment on this by those intimately conversant with gas would, I think, be that with the good ventilating burners in the market, an expenditure far short of an electric light installation would have not only prevented vitiation of air by the gaslights, but have effected, in addition, an amount of ventilation which might have had a more important influence on the health of the workpeople than even the installation of electric lighting. Secondly (and this is perhaps the more important point of the two), there is the question of comparative cost. The only detailed statement on this head in Prof. Fleming's lecture is where particulars are given of what is known as the cheapest form of electric lighting, viz., the arc. The figures are 6¼d. per hour per lamp of 2,000-candle light. It is subsequently stated that this nominal 2,000 candle-power can be taken as 1,000-candle actual, and that to secure the same light from gas, '400 cubic feet per hour would have to be burnt in a good burner, and this at 2s. 6d. per 1,000ft. is 1s.' Now 400 cubic feet of gas to produce a light of 1,000 candles is only an allowance of 2·5 candles per cubic foot of gas burned, when it is a well known fact that such a performance (with 16 candle gas) is worthy only of the commonest and crudest forms of burners. Had the comparison been made with an allowance only of 5 candles light per cubic foot, the cost of the 1,000-candle light becomes only 6d.; and there are regenerative burners in the market claiming a much higher power than this, effecting a proportionate decrease in the quantity of gas to be consumed in order to produce a required amount of light."

THE ELECTRIC LIGHT AT CADIZ.—The Maritime Exhibition at Cadiz, which the Duke of Edinburgh and the Mediterranean fleet visited some weeks ago, is fully in order. The electric lighting, which was undertaken by R. E. Crompton and Co. on the 24th July, started running on August 25th. The plant consists of three 16 horse-power Marshall's portable engines driving seven Crompton-Bürgin dynamos and three Crompton incandescent machines. These supply forty-two 3,000 candle-power arc lamps and 250 incandescent 16 candle-power lamps. Thirty-two arc lamps are placed in the grounds, and three in the machinery shed. The incandescents are distributed between the large central hall, the picture gallery, a small pavilion put up by the Spanish Steamship Company, and the temporary theatre used for the Italian Opera. Thirty-eight lamps for the stage of this theatre, including wiring, were put up in one day. This is at present the only theatre in Spain lighted by electricity. One 16 horse-power engine with two arc lamps and one incandescent machine are held in reserve in case of accident to the rest of the installation. The arc lamps are run in five circuits, viz., four of nine lamps and one of seven lamps. The Exhibition buildings consist of isolated pavilions of light but extremely elegant construction, the style of architecture being Moorish. The pavilions surround two large squares, which are divided in the centre by the grand hall (500ft. long); from the square, or, rather, crescent on the seaward side of this radiate seven smaller pavilions. These run out over the sea, their foundations being shaped like the bows of a vessel. The effect at night by the brilliant rays of the numerous arc lamps is pretty and fantastic in the extreme. Among the exhibits is a handsome showboard of the various telephones and magnetic bells manufactured by the Consolidated Telephone Construction and Maintenance Company. A considerable number of telephones of the Consolidated Company have been erected in Cadiz and Jerez, and have given every satisfaction. The whole work of the installation of the electric light has been carried out with great success and promptitude by Messrs. R. E. Crompton and Co., under their engineer, Mr. R. F. Hayward. We say this advisedly, because in this case, after the exchange of a few telegrams, one of the principals of the firm went over to Cadiz, and the contract was soon settled, whereas we have known valuable contracts lost on the Continent for want of a little energy and enterprise in London.

WESTON-SUPER-MARE.—The Thomson-Houston plant which has been at work at Weston-super-Mare during the summer has now ceased running, but it is hoped that before long arrangements may be made for its permanent employment. The close of the season was marked by a lecture on electric lighting, delivered by Mr. J. C. Wharton to a crowded audience at the Victoria Hall. The chair was taken by Mr. Wicksteed, who in the course of his remarks said that he had had the electric light in his own drawing room for the past month, and, with all in the house, felt when last Saturday night came that he was saying "good-bye" to a dear friend. He only hoped, however, that it was "*au revoir*" and not "adieu." He looked forward to the immediate future in which the light would be introduced into Weston-super-Mare. It would, he felt convinced, prove of benefit to the poorest and humblest as well as to their more well-to-do fellows; and the more of it that was used the cheaper it would become. Dr. Roxburgh said the electric light had been the feature of the season this year in Weston-super-Mare. He had noticed that the moon was quite put out by it several nights. One had only to walk along the Esplanade in the evening to see how much it was enjoyed by those who assembled there to listen to the music, its only disadvantage seeming to be the appearance it gave to the faces of the persons subjected to its rays. And in the High-street it was quite as much to be appreciated. He (Dr. Roxburgh) had been struck with Mr. Wharton's special pleading in regard to the point as to how gas shares would be affected by the electric light, Mr. Wharton having proved to demonstration that gas shares would largely increase in price as the result of the introduction of the electric light. Having made reference to a Birmingham musical festival at which he was present two years ago, and compared the comfort and vitality experienced at it by the performers and the audience on the nights when the town hall was illuminated with the electric light with the state of things that existed when the building was lighted with gas, the doctor observed that all ought to know that every gas burner used as much oxygen as three people, so that if there were six or eight burners in a dining room they would consume as much oxygen as eighteen or twenty-four persons. It was a demonstrated fact, demonstrated by experience as well as theory, that the electric light was infinitely preferable to gas. The following resolution was carried by acclamation:—"It is the feeling of this meeting that it would be to the interest of Weston-super-Mare, and add greatly to its attractiveness, thereby increasing its prosperity, to light the principal streets and the Esplanade with the Thomson-Houston system of electric lighting. The month's trial of this system has given great satisfaction to visitors and residents."

ABOUT LIGHTNING.—There is an opinion prevalent among the public that lightning does not strike twice in the same place. This, however, is a fallacy, as it is well known to those who study electrical phenomena that lightning does strike in the same place more than once, and that it will fall upon a certain place just as often as the natural conditions are such as to determine the lightning discharge to that point, or just as often as that place lies within and forms the path of least resistance. Probably one of the best illustrations of numerous lightning discharges falling upon one place that has ever been recorded in the United States is upon the farm of Mr. W. F. French, who lives near Flushing, Genesee county, Mich. Mr. French is an industrious farmer, and from the numerous lightning visitations he has had, he might well ask, When and where will it end? In the summer of 1871 his barn was struck by lightning, doing but slight damage to the barn, but killing a fine team of horses, worth $400, which were in the barn at the time. In 1878 the same barn was again struck in exactly the same place, and another fine team, that he had refused $400 for, were killed while standing in the identical stalls occupied by the team that was killed in 1871. In 1884 a fine Clydesdale stallion, valued at $1,000, was struck and killed, and during the present summer he lost another valuable horse, valued at $200, which was struck while grazing in a field. At various times between the above disastrous strokes a great many trees were shattered, and it is a frequent occurrence for lightning to strike the earth in an open field, often tearing a hole in the ground. The great frequency with which lightning strikes upon this farm suggests forcibly that there must be some natural cause for it. The land is rolling, and a small stream meanders through one part of it. The soil varies, and there are several kinds of trees on the place, such as beech, maple, oak, basswood, and ash. Mr. French states that he has found what he supposes to be an iron ore, but that he has never investigated the matter to learn the extent of the body of ore or ascertain its nature. I could cite many cases where lightning has struck several

Digitized by Google

times. No doubt many citizens remember the terrible accident at the Atlantic Flour Mills in St. Louis on August 12th, 1881. On the same day just five years later the new mill, now called the Regina Mill, was struck, but the conductors saved the building. The charge was a heavy one, as it wrenched the conductor leading to the earth on the north side loose. In St. Louis lightning falls more frequently in the vicinity of Main and Plum and in the neighbourhood of the Belcher Sugar Refinery than in any other portion of the city. I have noted this fact for the past seven years, and have records of many discharges in those districts, which happily did but slight damage.—*New York Electrical Review.*

JAMAICA.—The history of the connection of Jamaica with the system of submarine cables is given in "The Note Book of Jamaica," just published by Mr. Stanford, of Charing-cross, in which we find that in 1870 the West India and Panama Company obtained the transfer of the rights of the International Ocean Telegraph Company, and thereupon extended to the colony their telegraph system. The new company was aware that the local Government was unable to afford pecuniary support, and it was not till 1876 that they solicited a contribution from the Government approximate to the means of so important a part of the West Indian possessions. In reply, Sir William Grey expressed a hope that the Imperial Government would not be behindhand in stretching out a hand of assistance in upholding the Telegraph Company. No response was made to the suggestion for Imperial subsidy. In 1877, however, the Secretary of State for the Colonies recommended that Jamaica should give a subsidy of £3,000 per annum. Upon considering this proposition the Legislative Council agreed to give £1,000 per annum subsidy, on condition of publishing daily in Kingston a bulletin of news giving—

(1) Important political news from all parts of the world.
(2) Price of Colonial products in New York and London.
(3) Prices of staple articles of sale in the Colonies.
(4) Inter Colonial news.
(5) Movements of steamers, with the names of passengers for the West Indies.
(6) Official appointments, &c.

The company expressed their willingness to accept a subsidy of £2,000 per annum upon the considerations proposed by the Legislative Council, and this grant was sanctioned in 1879. In 1880 the Board of Directors deputed Mr. Richard C. Grosvenor to visit the West Indies in the interests of the company, and "to place before the several Governments the precarious position of the company's system in the West Indies, to see that the revenues derived from it are insufficient for its efficient maintenance, and to ask for a renewal of the Telegraph Acts with larger grants and modifications of the terms." In 1881, Mr. Grosvenor visited Jamaica to urge the proposals suggested by the company, while in 1882 representatives of the West India Colonies—to which no delegate was sent from Jamaica—convened at Barbadoes considered the question of subsidies, and made suggestions to Her Majesty's Government, which, after full consideration, they could not agree to. In 1886, Governor Sir Henry Norman laid a message before the Legislative Council with reference to the desire for some improvement in the telegraphic messages. He stated that it seemed inevitable that the messages should be compiled in New York to save cost of transmission across the Atlantic, and he also stated that while the messages must be adapted as far as possible to the requirements of all West Indian Colonies, the company was most willing to accept any practical suggestions for improvement that might be made from Jamaica. No action was taken, and the agreement of 1879 continued. It will be seen that the company throughout has been anxious to comply with the demands of the inhabitants as far as possible.

"UNDERWRITERS' WIRE."—We mentioned recently that the use of the insulated wire known in the States as "underwriters' wire," for electric lighting leads, had been expressly condemned in a resolution voted unanimously by the representatives of the American Edison Companies. So far as we are aware no specimen of this meretricious production has drifted to this side of the Atlantic, and many of our readers are therefore probably unaware of its nature. At the very beginning of electric lighting business in America the underwriters laid down a single condition with regard to the wiring—that the insulation must be uninflammable. It is needless to remark that this condition is a highly desirable one, but in practice it has usually to give way to some extent to the far more important question of adequate insulation, with which the underwriters did not suppose themselves to be immediately concerned. The study of the Phœnix Fire Office rules, to which the American offices have since betaken themselves, has doubtless tended to open their eyes upon this and many other points of a similar character. However, the dictum had gone forth, a fireproof insulation was demanded, and a fireproof *covering* was speedily placed on the market. The fact that the material was more or less incombustible being easily demonstrated, the further question of whether or not it possessed any insulating property worth speaking of was left for experience to determine. Experience has now settled the question, with the result embodied in the resolution referred to. The material known as underwriters' wire consisted of a cotton braid, painted with white lead. Cotton, as every electrical student is aware, is in itself an excellent insulator—the only, but sufficient, objection is that cotton when exposed in any degree to the atmosphere cannot be induced to remain in a moderately dry condition, and *damp* cotton is one of the most undesirable materials to employ for the purpose in view. The notion that this difficulty might be overcome by the addition of white lead as a paint is one which might, perhaps, fairly have been made the subject of preliminary trial, but that the material should have come into such extensive use (in America) as to have received a practical demonstration on the scale of some 100 or more disasters caused thereby is decidedly matter for regret. We give the above figure on the authority of Mr. Barrett, the well-known electrician to the City of Chicago. Mr. Barrett, in a paper which he read before the recent Convention of the National Association of Fire Engineers at Atlanta, stated that he had recently addressed a series of questions on the subject of electricity to the local authorities in the principal cities of America, from which he gathered that there had been hitherto 137 fires caused in this way, resulting in the loss of $1,165,336. Mr. Barrett was evidently of opinion that the greater portion of these accidents were due to the employment of underwriters' wire. We hasten to add, for the benefit of any of the outside public whom this paragraph may reach, that the wire in question is, we believe, absolutely unknown in this country, and further that wherever installations are carried out in accordance with the regulations known as the Phœnix Fire Office rules (which are almost universally followed in this country) no damage from fire caused by electric lighting has ever been known to occur.

THE EMPLOYMENT OF A SHUNT WITH THE BALLISTIC GALVANOMETER.

BY E. C. RIMINGTON.

If two quantities of electricity are to be compared by means of a ballistic galvanometer, and one of them is much greater than the other, it is generally necessary to shunt the galvanometer when the larger quantity is discharged through it, so as to obtain the throws about the same in each case. If the quantities which are passed through the galvanometer are obtained from the discharge of a condenser, it is well known that the value of the multiplying power of the shunt can be written $\frac{G+S+k}{S}$, where G is the resistance of the galvanometer, S that of the shunt, and k is a constant depending only on the galvanometer, and which can be obtained by experiment, so that the galvanometer behaves as if it had a resistance $G+k$ instead of G. When, however, the quantity to be measured is obtained by altering the value of the magnetic field within a coil, which is connected to the shunted galvanometer, the case is somewhat different, and may be investigated in the manner shown in Fig. 1.

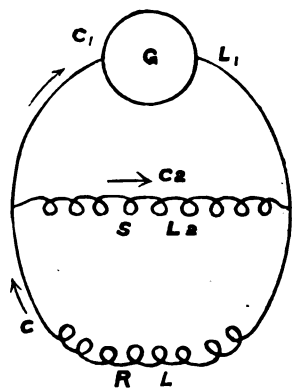

FIG. 1.

Let G, S, and R represent the resistances of the galvanometer, shunt, and coil; let L_1, L_2, and L be their coefficients of self-induction; suppose them to be so placed that the co-efficient of mutual induction between any two of them is zero, as would be the case in practice. Let E be the E.M.F. acting in the coil at any instant, and let C_1, C_2, and C be the currents in the galvanometer, shunt, and coil at the same instant. Then we have:

$$C = C_1 + C_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$C R + C_2 S + L\frac{dC}{dt} + L_2\frac{dC_2}{dt} = E \quad . \quad . \quad . \quad (2)$$

$$C_1 G - C_2 S + L_1\frac{dC_1}{dt} - L_2\frac{dC_2}{dt} + a\,.\,\frac{d\sin x}{dt} = 0 \quad . \quad (3)$$

$a\,.\,\frac{d\sin x}{dt}$ represents the E.M.F. induced in the coils of the galvanometer by the motion of the needle.

The number of lines of force due to the needle which pass through the galvanometer coils is proportional to $\sin x$, and consequently the E.M.F. induced in them to $\frac{d\sin x}{dt}$, or is equal to $a\frac{d\sin x}{dt}$, where x is the angle the needle makes with the plane of the coils and a is a constant depending on the geometry of the coils and the magnetic moment of the needle.

From (1) and (3)—

$$C_1(G+S) - CS + L_1\frac{dC_1}{dt} - L_2\frac{dC_2}{dt} + a\frac{d\sin x}{dt} = 0.$$

$$(G+S)\int C_1\,dt - S\int C\,dt + L_1\int dC_1 - L_2\int dC_2 + a\int d\sin x = 0.$$

If this be integrated between the limits time equals zero and the time when the needle is at the end of its first throw, $\int C_1\,dt = q_1$, the quantity passing through the galvanometer; $\int C\,dt = Q$, the total quantity which passes through the circuit; $\int dC_1$ and $\int dC_2$, both equal zero because, by supposition, the time the E.M.F. acts in the coil R must be very small compared to the time of swing of the galvanometer; also the E.M.F. due to the swinging needle is zero at the end of a throw, as at that point the needle is at rest. $\int d\sin x = \sin\delta$, where δ is the throw obtained. So we have

$$(G+S)q_1 - SQ + a\sin\delta - 0.$$

Now, if the galvanometer employed be a reflecting one, δ will always be a small angle, and consequently $\sin\delta = 2\sin\frac{\delta}{2}$ approximately; but, by the principle of the ballistic galvanometer, $\sin\frac{\delta}{2}$ is proportional to the quantity that passes through the instrument, so we may write $\sin\delta = bq_1$; b is a constant depending on the geometry of the coil, the magnetic moment of the needle, and the controlling field.

Therefore $(G+S)q_1 - SQ + abq_1 = 0$;

or, $Q = q_1\frac{G+S+k}{S}$ (4) where $k = ab$ and depends only on the galvanometer.

Again, from equations (1) and (2),

$$(R+S)\int C\,dt - S\int C_1\,dt + L_2\int dC_2 + L\int dC = \int E\,dt$$

$$(R+S)Q - Sq_1 = \int E\,dt.$$

Now, $$\frac{\int E\,dt}{R+\frac{GS}{G+S}} = Q_0,$$

the total quantity which would pass through the circuit if there were no motion of the galvanometer needle.

Therefore $$(R+S)Q - Sq_1 = Q_0\left(R+\frac{GS}{G+S}\right),$$

or $$Q = \frac{Q_0\left(R+\frac{GS}{G+S}\right)+q_1S}{R+S} \quad . \quad . \quad . \quad . \quad (5)$$

From (4) and (5)

$$\frac{Q_0\left(R+\frac{GS}{G+S}\right)+q_1S}{R+S} = q_1\frac{G+S+k}{S};$$

$$Q_0 = q_1\left\{\frac{(G+S+k)(R+S)}{S} - S\right\}\cdot\frac{G+S}{R(G+S)+GS},$$

$$= q_1\frac{G+S}{S}\cdot\frac{R(G+S)+GS+k(R+S)}{R(G+S)+GS},$$

$$= q_1\frac{G+S}{S}\left\{1+\frac{k(R+S)}{R(G+S)+GS}\right\},$$

$$= q_1\cdot\frac{G+S}{S}\cdot\left(1+\frac{k}{G+\frac{RS}{R+S}}\right).$$

Now, $$\int E\,dt = Q_0\cdot\left(R+\frac{GS}{G+S}\right) = Q_0\cdot\frac{R(G+S)+GS}{G+S};$$

$$\therefore \int E\,dt = q_1\cdot\frac{R(G+S)+GS+k(R+S)}{S},$$

$$= q_1\cdot\frac{(G+k)(R+S)+RS}{S}.$$

If $S = \infty$ or the galvanometer is unshunted

$$Q_0 = q_1\cdot\frac{G+R+k}{G+R}, \text{ and } \int E\,dt = q_1(G+k+R).$$

Again, if $R = \infty$

$$Q_0 = q_1\frac{G+S+k}{S};$$

this is the case of a condenser discharged through a shunted galvanometer.

Digitized by Google

To find k, charge a condenser and discharge it through the unshunted galvanometer obtaining a throw, D; again charge the condenser to the same potential difference as before and discharge it through the galvanometer, the latter being shunted with a resistance, S; let the throw be d; then, since the total quantity passing in both cases is the same

$$D = d\,\frac{G+k+S}{S},$$

or $$G+k = S\,.\,\frac{D-d}{d};\ \text{and}\ k = S\,\frac{D-d}{d} - G.$$

Call $G+k$ the apparent resistance of the galvanometer G_1; suppose an error x is made in the estimation of d, and y is the corresponding error in G_1;

$$G_1 - y = S\,\frac{D-(d+x)}{d+x};$$

$$y = S\left\{\frac{D-d}{d} - \frac{D-(d+x)}{d+x}\right\} = \frac{S\,D\,x}{d^2},$$

since $d\,(d+x) = d^2$ approximately, as x is small compared to d.

The fractional error in G_1 or $\dfrac{y}{G_1} = \dfrac{\dfrac{S\,D\,x}{d^2}}{\dfrac{S\,(D-d)}{d}} = \dfrac{D\,x}{d\,(D-d)}$.

To make $\dfrac{y}{G_1}$ a minimum, $d\,(D-d)$ must be a maximum, since $D\,x$ is constant. Now it is well known that $d\,(D-d)$ is a maximum when $d = D-d$, *i.e.*, when $d = \dfrac{D}{2}$. So in determining the value of k we should make S of such a value that d is about half D.

Another, and perhaps better, method of determining k is either to increase the capacity, or, keeping the capacity constant, to increase the potential difference of the condenser when the galvanometer is shunted so as to obtain the throws about equal.

First, increasing the capacity, let K_1 be the capacity when no shunt is employed, K_2 that with a shunt, and E the E.M.F. of the charging battery. Let D_1 and D_2 be the throws obtained without shunt and with shunt respectively—

$$E\,K_1 = a\,D_1,\ \text{and}\ E\,K_2 = a\,D_2\,\frac{G+S+k}{S},\ a\ \text{being constant};$$

$$\frac{K_2}{K_1} = \frac{D_2}{D_1}\,.\,\frac{G+k+S}{S};$$

$$G+k = S\,.\,\frac{D_1\,.\,\dfrac{K_2}{K_1} - D_2}{D_2},\ \text{and}\ k = S\,.\,\frac{D_1\,\dfrac{K_2}{K_1} - D_2}{D_2} - G.$$

Second, increasing the potential difference. This can best be done by circuiting the battery through a high resistance, and charging the condenser by connecting it to two points on this resistance. Let R_1 be the resistance between A and B, and R_2 that between A and C. When the galvanometer is unshunted connect the front contact of the key to B, and when shunted to C. As the capacity is the same in both cases the charges are proportional to the potential differences; but the potential difference between A and B is to the potential difference between A and C as R_1 is to R_2.

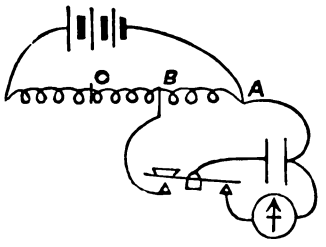

FIG. 2.

So $$\frac{R_2}{R_1} = \frac{D_2}{D_1}\,.\,\frac{G+k+S}{S},$$

and $$k = S\,.\,\frac{D_1\,.\,\dfrac{R_2}{R_1} - D_2}{D_2} - G.$$

THE LATE MR. CHARLES MOSELEY.

The *Manchester Guardian* announces the death at the age of 48 of Mr. Charles Moseley, which took place on Saturday last at Manchester. Manchester has given birth to few more remarkable men than Mr. Moseley. Mr. Charles Moseley was for many years little known to the general public. It was not until some eight or nine years ago that his interest in the telephone induced him to step forward into public life. He at one time contemplated establishing a private telephonic exchange in Manchester, but after the amalgamation of the Edison and Bell companies he was induced to accept overtures from the Lancashire and Cheshire Company, which resulted in his appointment as their chairman. In nothing was his energy more displayed than in a contest with the Post Office, who strove, under the Telegraphs Act, to prevent the establishment of telephonic communication between adjoining towns. Mr. Moseley put himself in correspondence with the various Parliamentary representatives of the district, and so convincing were his arguments that from time to time questions were asked in the House which Mr. Fawcett had great difficulty in answering. Subsequently Mr. Moseley had frequent interviews with the Postmaster-General, and it is not too much to say that he succeeded in converting him almost entirely to his views. As a result the present "trunk line" system has been developed, by which it is possible for most of the Lancashire towns to hold telephonic communication with each other. Since that time Mr. Charles Moseley has been one of the most noticeable persons connected with Manchester life. When the Edison Electric Light Company was formed his interest in electricity induced him to take a leading position as a director, and his own residence was lighted throughout by electricity.

He subsequently took a leading part in arranging for the Manchester Jubilee Exhibition. Mr. Moseley was ever ready to give counsel and aid where these were deserved. A hard worker himself, he had no sympathy with idleness in any form. But struggling worth or undeserved misfortune never appealed to him in vain. Hardly a day passed in which he was not asked to assist in the development of some new invention or to forward some fresh scheme of commercial enterprise, and he was the life and soul of other enterprises than the Chapelfield Works, with which his name is principally associated.

At a special meeting of the directors of the Lancashire and Cheshire Telephonic Exchange Company, held on Tuesday, the death of the chairman of the company, Mr. Charles Moseley, was formally announced, when it was moved by Mr. Alderman Joseph Thompson—"That the Board of the Lancashire and Cheshire Telephonic Exchange Company (Limited) has heard with the deepest grief of the death of their chairman, Mr. Charles Moseley, a gentleman who combined great business aptitudes with invariable courtesy, good humour, and strict integrity. The Board wish to place it on record that the success of the company is largely due to Mr. Moseley's unwearied efforts on its behalf. His practical knowledge of electricity and its adaptability to commercial purposes, his hopefulness, his business habits, and his popularity, made him peculiarly valuable as the leader and director of a new industry. The directors respectfully tender to Mrs. Moseley their heartfelt condolence under her great bereavement, and if it is any consolation to her to hear of the high esteem felt for her beloved husband, they can assure her that their fellow citizens regard Mr. Moseley's death as a great loss to the town; to the directors it is irreparable."

At a meeting of the Overseers of the Poor of the township of Ardwick, held on Tuesday, it was resolved: "That this Board desire to record their deep regret at the loss they have sustained in the death of Mr. Charles Moseley, whose assiduous care has watched over the interests of the township for the past twelve years. They desire at the same time to record their sympathy with Mrs. Moseley, and trust that time will mitigate the sorrow she cannot but feel under the bereavement she has so suddenly been called upon to bear."

THE EMPLOYMENT OF A SHUNT WITH THE BALLISTIC GALVANOMETER.

BY E. C. RIMINGTON.

If two quantities of electricity are to be compared by means of a ballistic galvanometer, and one of them is much greater than the other, it is generally necessary to shunt the galvanometer when the larger quantity is discharged through it, so as to obtain the throws about the same in each case. If the quantities which are passed through the galvanometer are obtained from the discharge of a condenser, it is well known that the value of the multiplying power of the shunt can be written $\frac{G+S+k}{S}$, where G is the resistance of the galvanometer, S that of the shunt, and k is a constant depending only on the galvanometer, and which can be obtained by experiment, so that the galvanometer behaves as if it had a resistance $G+k$ instead of G. When, however, the quantity to be measured is obtained by altering the value of the magnetic field within a coil, which is connected to the shunted galvanometer, the case is somewhat different, and may be investigated in the manner shown in Fig. 1.

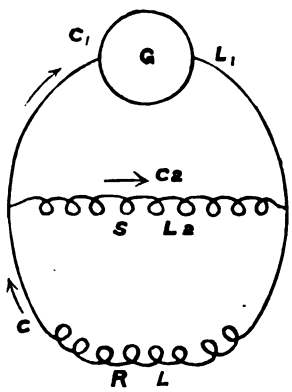

Fig. 1.

Let G, S, and R represent the resistances of the galvanometer, shunt, and coil; let L_1, L_2, and L be their coefficients of self-induction; suppose them to be so placed that the co-efficient of mutual induction between any two of them is zero, as would be the case in practice. Let E be the E.M.F. acting in the coil at any instant, and let C_1, C_2, and C be the currents in the galvanometer, shunt, and coil at the same instant. Then we have:

$$C = C_1 + C_2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$C\,R + C_2\,S + L\frac{dC}{dt} + L_2\frac{dC_2}{dt} = E \quad . \quad . \quad . \quad (2)$$

$$C_1\,G - C_2\,S + L_1\frac{dC_1}{dt} - L_2\frac{dC_2}{dt} + a\,.\,\frac{d\sin x}{dt} = 0 \quad . \quad (3)$$

$a\,.\,\frac{d\sin x}{dt}$ represents the E.M.F. induced in the coils of the galvanometer by the motion of the needle.

The number of lines of force due to the needle which pass through the galvanometer coils is proportional to $\sin x$, and consequently the E.M.F. induced in them to $\frac{d\sin x}{dt}$, or is equal to $a\frac{d\sin x}{dt}$, where x is the angle the needle makes with the plane of the coils and a is a constant depending on the geometry of the coils and the magnetic moment of the needle.

From (1) and (3)—

$$C_1(G+S) - CS + L_1\frac{dC_1}{dt} - L_2\frac{dC_2}{dt} + a\frac{d\sin x}{dt} = 0.$$

$$(G+S)\int C_1\,dt - S\int C\,dt + L_1\int dC_1 - L_2\int dC_2 + a\int d\sin x = 0.$$

If this be integrated between the limits time equals zero and the time when the needle is at the end of its first throw, $\int C_1\,dt = q_1$, the quantity passing through the galvanometer; $\int C\,dt = Q$, the total quantity which passes through the circuit; $\int dC_1$ and $\int dC_2$, both equal zero because, by supposition, the time the E.M.F. acts in the coil R must be very small compared to the time of swing of the galvanometer; also the E.M.F. due to the swinging needle is zero at the end of a throw, as at that point the needle is at rest. $\int d\sin x = \sin\delta$, where δ is the throw obtained. So we have

$$(G+S)\,q_1 - S\,Q + a\sin\delta - 0.$$

Now, if the galvanometer employed be a reflecting one, δ will always be a small angle, and consequently $\sin\delta = 2\sin\frac{\delta}{2}$ approximately; but, by the principle of the ballistic galvanometer, $\sin\frac{\delta}{2}$ is proportional to the quantity that passes through the instrument, so we may write $\sin\delta = bq_1$; b is a constant depending on the geometry of the coil, the magnetic moment of the needle, and the controlling field.

Therefore $(G+S)\,q_1 - S\,Q + ab\,q_1 = 0$;

or, $Q = q_1\frac{G+S+k}{S}$ (4) where $k = ab$ and depends only on the galvanometer.

Again, from equations (1) and (2),

$$(R+S)\int C\,dt - S\int C_1\,dt + L_2\int dC_2 + L\int dC = \int E\,dt$$

$$(R+S)\,Q - S\,q_1 = \int E\,dt.$$

Now, $$\frac{\int E\,dt}{R + \frac{GS}{G+S}} = Q_0,$$

the total quantity which would pass through the circuit if there were no motion of the galvanometer needle.

Therefore $$(R+S)\,Q - S\,q_1 = Q_0\left(R + \frac{GS}{G+S}\right),$$

or $$Q = \frac{Q_0\left(R + \frac{GS}{G+S}\right) + q_1 S}{R+S} \quad . \quad . \quad . \quad . \quad (5)$$

From (4) and (5)

$$\frac{Q_0\left(R + \frac{GS}{G+S}\right) + q_1 S}{R+S} = q_1\frac{G+S+k}{S};$$

$$Q_0 = q_1\left\{\frac{(G+S+k)(R+S)}{S} - S\right\}\cdot\frac{G+S}{R(G+S)+GS},$$

$$= q_1\frac{G+S}{S}\cdot\frac{R(G+S)+GS+k(R+S)}{R(G+S)+GS},$$

$$= q_1\frac{G+S}{S}\left\{1 + \frac{k(R+S)}{R(G+S)+GS}\right\},$$

$$= q_1\cdot\frac{G+S}{S}\cdot\left(1 + \frac{k}{G + \frac{RS}{R+S}}\right).$$

Now, $$\int E\,dt = Q_0\cdot\left(R + \frac{GS}{G+S}\right) = Q_0\cdot\frac{R(G+S)+GS}{G+S};$$

$$\therefore \int E\,dt = q_1\cdot\frac{R(G+S)+GS+k(R+S)}{S},$$

$$= q_1\cdot\frac{(G+k)(R+S)+RS}{S}.$$

If $S = \infty$ or the galvanometer is unshunted

$$Q_0 = q_1\cdot\frac{G+R+k}{G+R}, \text{ and } \int E\,dt = q_1(G+k+R).$$

Again, if $R = \infty$

$$Q_0 = q_1\frac{G+S+k}{S};$$

this is the case of a condenser discharged through a shunted galvanometer.

Digitized by Google

To find k, charge a condenser and discharge it through the unshunted galvanometer obtaining a throw, D; again charge the condenser to the same potential difference as before and discharge it through the galvanometer, the latter being shunted with a resistance, S; let the throw be d; then, since the total quantity passing in both cases is the same

$$D = d\,\frac{G+k+S}{S},$$

or $$G+k = S\,.\,\frac{D-d}{d};\ \text{and}\ k = S\,\frac{D-d}{d} - G.$$

Call $G+k$ the apparent resistance of the galvanometer G_1; suppose an error x is made in the estimation of d, and y is the corresponding error in G_1;

$$G_1 - y = S\,\frac{D-(d+x)}{d+x};$$

$$y = S\left\{\frac{D-d}{d} - \frac{D-(d+x)}{d+x}\right\} = \frac{S\,D\,x}{d^2},$$

since $d\,(d+x) = d^2$ approximately, as x is small compared to d.

The fractional error in G_1 or $\dfrac{y}{G_1} = \dfrac{\dfrac{S\,D\,x}{d^2}}{\dfrac{S\,(D-d)}{d}} = \dfrac{D\,x}{d\,(D-d)}$.

To make $\dfrac{y}{G_1}$ a minimum, $d\,(D-d)$ must be a maximum, since $D\,x$ is constant. Now it is well known that $d\,(D-d)$ is a maximum when $d = D-d$, *i.e.*, when $d = \dfrac{D}{2}$. So in determining the value of k we should make S of such a value that d is about half D.

Another, and perhaps better, method of determining k is either to increase the capacity, or, keeping the capacity constant, to increase the potential difference of the condenser when the galvanometer is shunted so as to obtain the throws about equal.

First, increasing the capacity, let K_1 be the capacity when no shunt is employed, K_2 that with a shunt, and E the E.M.F. of the charging battery. Let D_1 and D_2 be the throws obtained without shunt and with shunt respectively—

$$E\,K_1 = a\,D_1,\ \text{and}\ E\,K_2 = a\,D_2\,\frac{G+S+k}{S},\ a\ \text{being constant};$$

$$\frac{K_2}{K_1} = \frac{D_2}{D_1}\,.\,\frac{G+k+S}{S};$$

$$G+k = S\,.\,\frac{D_1\,.\,\dfrac{K_2}{K_1} - D_2}{D_2},\ \text{and}\ k = S\,.\,\frac{D_1\,\dfrac{K_2}{K_1} - D_2}{D_2} - G.$$

Second, increasing the potential difference. This can best be done by circuiting the battery through a high resistance, and charging the condenser by connecting it to two points on this resistance. Let R_1 be the resistance between A and B, and R_2 that between A and C. When the galvanometer is unshunted connect the front contact of the key to B, and when shunted to C. As the capacity is the same in both cases the charges are proportional to the potential differences; but the potential difference between A and B is to the potential difference between A and C as R_1 is to R_2.

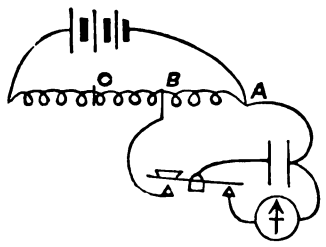

FIG. 2.

So $$\frac{R_2}{R_1} = \frac{D_2}{D_1}\,.\,\frac{G+k+S}{S},$$

and $$k = S\,.\,\frac{D_1\,.\,\dfrac{R_2}{R_1} - D_2}{D_2} - G.$$

THE LATE MR. CHARLES MOSELEY.

The *Manchester Guardian* announces the death at the age of 48 of Mr. Charles Moseley, which took place on Saturday last at Manchester. Manchester has given birth to few more remarkable men than Mr. Moseley. Mr. Charles Moseley was for many years little known to the general public. It was not until some eight or nine years ago that his interest in the telephone induced him to step forward into public life. He at one time contemplated establishing a private telephonic exchange in Manchester, but after the amalgamation of the Edison and Bell companies he was induced to accept overtures from the Lancashire and Cheshire Company, which resulted in his appointment as their chairman. In nothing was his energy more displayed than in a contest with the Post Office, who strove, under the Telegraphs Act, to prevent the establishment of telephonic communication between adjoining towns. Mr. Moseley put himself in correspondence with the various Parliamentary representatives of the district, and so convincing were his arguments that from time to time questions were asked in the House which Mr. Fawcett had great difficulty in answering. Subsequently Mr. Moseley had frequent interviews with the Postmaster-General, and it is not too much to say that he succeeded in converting him almost entirely to his views. As a result the present "trunk line" system has been developed, by which it is possible for most of the Lancashire towns to hold telephonic communication with each other. Since that time Mr. Charles Moseley has been one of the most noticeable persons connected with Manchester life. When the Edison Electric Light Company was formed his interest in electricity induced him to take a leading position as a director, and his own residence was lighted throughout by electricity.

He subsequently took a leading part in arranging for the Manchester Jubilee Exhibition. Mr. Moseley was ever ready to give counsel and aid where these were deserved. A hard worker himself, he had no sympathy with idleness in any form. But struggling worth or undeserved misfortune never appealed to him in vain. Hardly a day passed in which he was not asked to assist in the development of some new invention or to forward some fresh scheme of commercial enterprise, and he was the life and soul of other enterprises than the Chapelfield Works, with which his name is principally associated.

At a special meeting of the directors of the Lancashire and Cheshire Telephonic Exchange Company, held on Tuesday, the death of the chairman of the company, Mr. Charles Moseley, was formally announced, when it was moved by Mr. Alderman Joseph Thompson—"That the Board of the Lancashire and Cheshire Telephonic Exchange Company (Limited) has heard with the deepest grief of the death of their chairman, Mr. Charles Moseley, a gentleman who combined great business aptitudes with invariable courtesy, good humour, and strict integrity. The Board wish to place it on record that the success of the company is largely due to Mr. Moseley's unwearied efforts on its behalf. His practical knowledge of electricity and its adaptability to commercial purposes, his hopefulness, his business habits, and his popularity, made him peculiarly valuable as the leader and director of a new industry. The directors respectfully tender to Mrs. Moseley their heartfelt condolence under her great bereavement, and if it is any consolation to her to hear of the high esteem felt for her beloved husband, they can assure her that their fellow citizens regard Mr. Moseley's death as a great loss to the town; to the directors it is irreparable."

At a meeting of the Overseers of the Poor of the township of Ardwick, held on Tuesday, it was resolved: "That this Board desire to record their deep regret at the loss they have sustained in the death of Mr. Charles Moseley, whose assiduous care has watched over the interests of the township for the past twelve years. They desire at the same time to record their sympathy with Mrs. Moseley, and trust that time will mitigate the sorrow she cannot but feel under the bereavement she has so suddenly been called upon to bear."

CONCERNING ELECTRICAL ENGINEERS.

Our mention last week of an American example which it would be wise if the Electrical Engineers of this country were to follow has met with such favourable attention, and the suggestion we ventured to put forward in relation to it has called forth so many responses, both oral and in writing, that we think it worth while to speak more at length of the scheme while it is fresh in the minds of our readers. It was the American Electric Light Convention that gave rise to the idea, a Convention which is already doing good practical service in the States, and if imitated here on the broader basis which the circumstances of this country seem to demand, would be not less advantageous to British Electrical Engineers. That something of the kind has long been felt to be needed is testified by our correspondence columns, where from time to time discussions on questions arise that can be thrashed out thoroughly only by that personal intercourse and comparison of experience which a public meeting or convention adequately affords. The questions to which we are now alluding are almost exclusively of the practical sort, neither theoretical nor scientific, though of course these latter elements are not excluded by the fact that the conditions of practical work would be esteemed of primary importance by practical men. Neither the meetings of the Society of Telegraph-Engineers and Electricians, nor of any other society that we can call to mind, at all provide what we are desiderating, namely, the bringing together of business men to discuss and promote the special callings in which they are engaged.

The Electric Light business in America is already so extensive that it can command a very respectable "Convention" all to itself. This would probably not be the case in England, where any assembly of the kind might properly include not only Electric Light but Electric Locomotive and Electric Telegraph and Telephone-Engineers. And what we suggest is that they should combine to at least this extent, namely, to meet either as a body or by delegation once or twice a year in order to consider how best they may protect and advance their corporate interests. We have examples of such combination even on this side of the Atlantic. The Mechanical Engineers and the Iron and Steel Institute are illustrations of what we mean, neither of which clash in any way with the Institution of Civil Engineers, the functions of which, like those of the Society of Telegraph-Engineers, being scientific and professional rather than commercial. The aim of Societies like those just named may be roughly described as that of providing their members with the equipments of their trade; the aim of the subsidiary Association or Convention the formation of which we are advocating would be, on the other hand, to turn that professional equipment to the best account, and would consequently be welcome to members of various and differing Societies. In this respect it would resemble the meeting of the British Association; but, unlike that miscellaneous gathering, its object would be not to promote either science or business in general, but a particular business representing a particular branch of applied science.

The term Convention, which the Americans have borrowed from the French, is not altogether adapted for English use. It is at once too big and too little, smacking rather of the Revolution at one extreme and the Caucus at the other. Association would be equally explanatory of its object, and besides being more accurately descriptive of its organisation would be more friendly and co-operative in its signification. We all know that an Association meets for a common object; the Associated Chambers of Commerce answers this description pretty exactly. Nobody knows beforehand what a Convention may be convened to say or do; and the historical example above alluded to, separating to cut each other's throats, is not a point in its favour. But, whatever its designation, the assembly might be easily organised, and the expenses attending it would be quite trivial. Let a beginning be made as soon as practicable; a committee formed, a secretary appointed, and a meeting called, adherents will speedily come in. An Association of Electrical Engineers has on the face of it an inviting look to the practical eye, and we feel pretty confident that in a very short time such an Association would muster a very strong roll of members.

In our comments on the American "Convention" we observed that the scientific papers on electric lighting, to which it is almost exclusively devoted, are not of a very high order. It is no disparagement to say this in the case of America, because we know that much allowance has to be made for keeping up the oratorical standard, and that science lends itself to this object almost as readily as politics, though not often with such edifying results. There is no fear of our proposed Association yielding to the temptation of high science or high faluting of any kind if its practical objects be steadily kept in view from the outset. It is needless to enumerate what those objects are to be, they will arise as circumstances may determine; but subjects of great and immediate importance are ripe for discussion even at this moment. For example, there is the Electric Lighting Act, there is the local opposition to Telephone Wires and Electrical Railroads, and there are the Fire Insurance Rules. It is an open secret that the provisions of Mr. Chamberlain's Act were originally accepted, if not actually

Digitized by Google

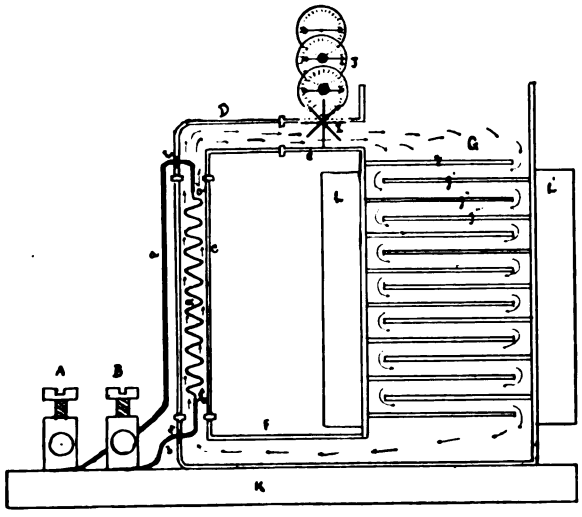
suggested, by electrical engineers, who, with no doubt the best intentions, gave it their approval on the supposition that it was better than no Act at all, but who, had there existed any cohesion in the profession or opportunity for a full discussion, would certainly have acted quite differently. The reform of this measure is urgently needed, and the shape it ought to take can only be settled satisfactorily by mutual and friendly interchange of views among those whom it chiefly concerns. And in this way, too, their relations with local authorities, often very strained and captious, would be placed on a sound footing. As touching the regulations for installations in respect to fire risks, it is high time the question was settled whether the Phœnix rules are to be recognised as obligatory all round, or whether some other authority is to be allowed to step in and make matters more confusing than ever. With such questions as these the members of a corporate body could deal decisively and with full regard to their own interests; as separated individuals they can do nothing.

CORRESPONDENCE.

ANOTHER CURRENT METER.

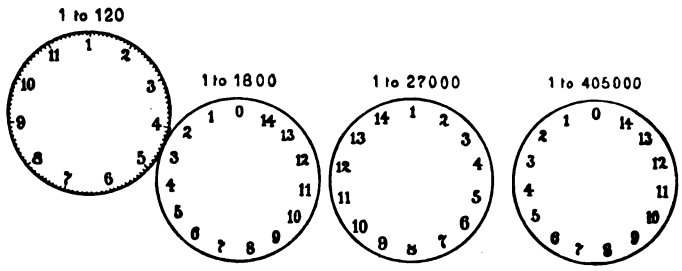
TO THE EDITOR OF THE ELECTRICIAN.

SIR: Your paper of the 23rd inst. has just arrived, and reading the interesting article of Prof. Forbes upon his current meter, we wish to give you a description of a meter we made in June, 1883. Enclosed you will find a cross section of the



Cross Section of Jehl and Rupp's Current Meter

meter and also a printed dial we had made at the time. We called it an ampere register, but no doubt we would give it a better name to-day. The meter consisted of a glass tube, *c*, both ends of which were fitted into two bent pieces of piping, D and F, as shown. Through these bent tubes D and F passed the wires *a* and *b*, which were connected to the binding posts A and B. The part of the wire where it passed into the tubes was well insulated. At the ends *a'* and *b'* was connected the coil R, which consisted simply of a few turns of copper wire whose diameter was less than the leading wires *a* and *b*. To the tube D was attached a square tube, E, which had a little opening at the top so as to permit a small undershot wheel, I, to revolve freely. This undershot wheel was well pivoted and constructed very light. To the axis of this wheel was connected another system of wheels with indicators, as shown, J. Now, the tubes E and F were connected to a reservoir, G. This reservoir consisted of a square tank, in the inside of which were soldered in an alternating manner square sheets of copper as shown in the drawing *g g' g'' g'''* . . . . These sheets acted as diffusers. These plates or sheets presented a very large surface. On the outside of the tank G were also diffusers *h h'* . . . . arranged all round and presenting an appearance as if two books were open so as to form a square with their covers, the leaves being the diffusers. The diffusers on the outside were at right angles to those inside.



Dial Face.

The action of the meter was thus:—When a current passes through the coil R it heats the liquid at the place, thus causing a circulation, the warm liquid ascending while the cold liquid descends as shown by the arrows. This circulation causes the undershot wheel to revolve, and its revolutions are registered by the clockwork. The stronger the current the more the heat, and thus the more rapid the circulation. The warm liquid once in the tank, which is of a reasonable size, will impart its heat to all the diffusers. The surface of the glass tube, &c., is very small in comparison to the surface of the tank. It will be seen that the function of this apparatus is independent of the outward temperature, for the motion of the liquid is due only to that heat which is generated by the current. When the current does not pass, it is evident that the liquid, at whatever temperature it may be, does not circulate, as all parts are of the same temperature, but the moment the current passes a difference is produced, which causes a circulation in proportion to the current. We may mention that we tried various liquids, and give preference to pure olive oil. It will also be seen that this meter is good for alternating currents. In conclusion, we may remark that the tests we made gave satisfaction, and we wanted to publish them, but that Mr. Jehl was called away to fit up the Edison exhibit in the Vienna Exhibition for the Société Electrique Edison of Paris. After the exhibition we began our work upon our disc machine, and had almost forgotten our meter.—Yours, &c., JEHL AND RUPP.

Brünn, Sept. 26, 1887.

P.S.—The whole apparatus is mounted on a base, K.

TELEPHONIC INTERCOMMUNICATION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: On page 430 of last issue, under heading of "Western Counties Telephone Company," you speak of telephonic communication between towns as an "experiment."

Permit me to say that my company has had such an "experiment" in successful operation for several years. Out of our total length (at 30th June) of *7,253* miles of wire, no less that *2,400* is employed solely for inter-town work.

Quite 50 per cent. of our subscribers regularly use these trunk-wires, and our income from this source alone is at the rate of nearly *£7,000* per annum.

Referring to another matter alluded to in your paragraph, I may say that our subscribers have all along been allowed to telephone *direct from their own offices*. At the option of subscribers, payment can be made either by a fixed sum yearly in advance or by a toll per message. In the latter case the company keeps a record of the inter-town "calls," and furnishes a monthly account.

The popularity of this "toll" system may be judged from the fact that the aggregate of these subscribers' monthly accounts is at the rate of nearly *£3,000* per annum, and each month shows a steady increase.

The *yearly* rentals of trunk wires yield about *£2,200* per annum; the balance of the £7,000 above mentioned is paid by

Digitized by Google

the general public, for whose convenience we have opened more than one hundred call offices in our district.

By inserting this letter in your next issue you will oblige, Yours, &c.,

KENNETH MACIVER, Secretary and General Manager,
Lancashire and Cheshire Telephone Exchange Company (Limited).

38, Faulkner-street, Manchester, October 4, 1887.

[We need scarcely assure our correspondent that we are already fully aware of the success of inter-urban telephony in the North of England. The note referred to the introduction of the service in the less busy districts of the West, where it must for the time being be regarded as a financial "experiment."—ED. *E.*]

THE PROPOSED ASSOCIATION OF ELECTRICAL ENGINEERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice in your issue of the 30th ult. a suggestion that a Society of English Manufacturers and Practical Electricians—after the lines of the Electric Light Congress in America—would encourage business in electrical engineering on this side of the water. I cannot say that I know much about the doings or objects of the American Society, but it seems to me that if the discussions of the English Society were limited to the business done in England it would have very little to talk about. Any movement calculated to rouse the British lion out of his present torpid condition should meet with the support of all electricians, and such a society as you propose could, I believe, exercise a beneficial influence on electrical business by banding together electricians and contractors of standing, and using its influence to raise (more or less) the standard of work done by installation engineers. There are many installations of first importance in this country which are doubtful successes—not to mention those which have been abandoned altogether—and there is no doubt that these exercise a depressing influence on the state of electric lighting in this country.

I maintain that many of these failures are attributable to want of knowledge or experience on the part of the contractors. Persons who do not know anything about calculating out their sections for conductors, or suitability of certain dynamos or engines for the particular work in hand, rush in and set up an installation. They, in many cases, get good engines, good dynamos, good lamps, &c., and yet combine the whole in such a haphazard manner that the result is horrible. Sometimes it is simply the section of the conductors that is at fault, but sometimes it is a matter not quite so much on the surface. Thus, about a year ago I sent eight arc lamps designed for series burning with a current of 12 amperes to some installation engineers in the north. On starting the installation my friends wrote that the lights were not steady, and I went up north post haste. On arriving at the installation I found the lamps had a slow pulsation, going low, and then gaining brightness up to great brilliancy; then sinking gradually lower and lower, and then up again, the whole cycle taking place in about half a minute, and being repeated sometimes three or four times in succession, and sometimes only at intervals of two or three minutes. I saw what the matter was at once, and made my way to the engine shed. There I found a Fowler engine and Mather and Platt dynamo. Here was a very good set of plant; engine, dynamo, and lamps all very good, and yet giving abominable results. On looking at the ammeter I found, as I had anticipated, that the current was fluctuating between 15 and 8 amperes (as nearly as I can now remember).

The explanation is this:—My lamps were designed to feed at 12 amperes. The iron in the Mather and Platt dynamo was not magnetically saturated at 12 amperes, or, in other words, the terminal curve of E.M.F. was a rising one at 12 amperes, and since my lamps have a "pull back"—which every good lamp should have, Mr. De Wolffers notwithstanding—the combination was an impossible one. The obvious thing to do was to make the lamps feed at a higher current, which I did, altering them to feed at 15 amperes, when all the irregularities disappeared and the installation gave satisfaction. Of course, my friends should have specified to the dynamo makers that the machine should reach the summit of its curve of E.M.F. at the terminals at a lower current than 12 amperes (say 10—11). But one could hardly be annoyed with them for coming to grief in this respect a year ago, taking into consideration that it seems to be a point of honour among English installation engineers *not to know* anything at all about arc lights. However, the fact remains that an installation went very near being condemned, in which all the plant was high class, simply for the want of a little ordinary electrical knowledge.

I could give four more instances in which this very point has cropped up and damaged an arc installation; and if these five instances have come under my observation, how many must have occurred and possibly remained uncorrected, to the detriment of electric lighting?

Another *pons asinorum* of *soi disant* electricians is the coupling of compound-wound machines to work in parallel; but one might go on for ever through the list of unsuitable belts, engines of too slow speed, &c. My point is that a society having for its members sound practical electricians and engineers only, and striving to shake the practice of electrical engineering into something like an art, having some definitive rules and principles—not a sort of "go-as-you-please" business, as at present—and at the same time keeping an eye upon the work done by all installation engineers, whether members or outsiders, would be calculated to benefit and develop electric light in this country, and to such a society I should give my unqualified adherence.—Yours, &c,

J. GRICE STATTER.

P.S.—I should explain, for the benefit of those who are not electricians, that *all* dynamos used for driving arc lights should have reached the highest point of their curve of E.M.F at the terminals at a current somewhat less than that at which the lamps feed, and that my lamp is not in any way peculiar in this respect.

West Drayton, Oct. 3, 1887.

"WHAT IS ELECTRICITY?"

TO THE EDITOR OF THE ELECTRICIAN.

SIR: As you have found my paper, "What is Electricity?" of sufficient interest to publish an abstract of it, I think that you may be interested in some further remarks on the subject, the more especially as I find that my readers here have misapprehended some of my statements, and also your editorial remarks thereon.

My position is not that in a mathematical sense electricity cannot be expressed in terms of length, time and mass, but that being so expressed it does not follow that it is one of these, nor force, energy, or anything else except electricity.

My meaning will be made more apparent by an illustration. We can and do express energy graphically by an area, as in the pressure diagram of a steam engine. The co-ordinates being respectively equal numerically to the movement of the piston and the pressure, the area of the figure is numerically equal to the work done. Now, no one supposes in consequence that energy is really an area, or that the relation is anything more than a numerical one.

Much as I respect anything emanating from so profound a scientist as Prof. Tait, I can find no philosophical reason for regarding force as any more of a "cloud wrapped mystery" than energy.

Neither can I see, with the popular eye, any more mystery in electricity as a distinct entity than in heat.

To regard one of these phenomena as a starting point, and express the others in terms of it, may serve a useful purpose, but it does not prove that the other phenomena are but manifestations of the first, which is alone an objective reality.

That any scientific man should hold electricity (*e.g.*, quantity of electricity) to be energy seems to predicate that he must have some other unit than the electrostatic or electro-

Digitized by Google

magnetic units in his mind. The dimensions of energy are $[L^2M\,T^{-2}]$ of energy referred to unit of time $[L^2M\,T^{-3}]$.

The dimensions of quantity of electricity are in the electro static system $[L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-1}]$, and in the electro-magnetic system $[L^{\frac{1}{2}}M^{\frac{1}{2}}]$. In order to make up the dimensions of energy we must multiply these expressions by $[L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}]$ and $[L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-2}]$ respectively, which are exactly the respective dimensions of electromotive force in the two systems.

It is therefore the product of electricity and E.M.F. that is energy, and not electricity alone.

The dimensions of current are in the two systems $[L^{\frac{3}{2}}M^{\frac{1}{2}}T^{-2}]$ $[L^{\frac{1}{2}}M^{\frac{1}{2}}T^{-1}]$, which being multiplied by the respective dimension of E.M.F. gives the dimensions of energy per time $[L^2M\,T^{-3}]$, and we must still multiply by a time to get energy. Electricity regarded as a flux may be expressed as a surface integral in the same way as quantity of heat.

Now this quantity of heat is certainly energy; but it does not follow therefrom that electricity is energy, any more than the fact that an equation of similar form to the equation of continuity in hydro-dynamics holds true in the case of electric currents proves that electricity, like water, is a material, incompressible fluid. Similar arguments to the above apply to the case of the supposition that electricity is matter. It certainly is not mass, but if it is contended to be a kind of matter which possesses no mass or other attribute which would interfere with its being electricity I will offer no objection.

In regard to the Faraday and Maxwell theory of stress in a dielectric, I will say that the mathematics of stress may figure out ever so well, but as a vacuum acts as a dielectric, before we can say that a real stress exists we must first know whether a vacuum is really a vacant space or not.

Maxwell himself likens his theory to the process of differentiation, and the theory of attraction at a distance to integration. Is there any more objective reality to one process than the other?—Yours, &c., TOWNSEND WOLCOTT.

828, Monroe-street, Brooklyn, N.Y., U.S.A.

THE LIGHTING OF THEATRES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In lighting a theatre by electric light will some electrician kindly inform me what precautions are of avail to prevent a disastrous fire any time a wire is broken, as it is alleged that in such a case an arc light is at once set up between the broken ends which would speedily set on fire any articles of an inflammable nature in the neighbourhood?—Yours, &c., SAFETY.

October 1st, 1887.

ELECTROMAGNETIC INDUCTION AND ITS PROPAGATION.—XLVI.

BY OLIVER HEAVISIDE.

Cancelling of reflection by combined resistance and bridge. General remarks. True nature of the problem of long-distance telephony. How not to do it. Non-necessity of leakage to remove distortion under good circumstances, and the reason. Tails in a distortional circuit. Complete solutions.

Having in Sections XLIV. and XLV. discussed in some detail the effects due to resistances inserted in, and also those due to conducting bridges across, a non-distortional circuit, which are of fundamental importance, and which lead to the development of a positive tail by a continuous distribution of resistance in excess of the non-distortional amount, and of a negative tail by an excess of leakage, the full investigation of the case of resistance and leakage combined in any proportions presents no difficulty.

Start with a circuit having no resistance and no leakage, which is therefore both non-distortional and conservative (or characterised by the absence of attenuation), and let there be an isolated disturbance going from left to right, defined by $V_1 = Lv C_1$. Also, let there be, at a certain place X, a bridge across the circuit, of conductance k; and, at the same place, a resistance r inserted in the circuit. When our incident wave V_1 arrives at X, there result a reflected wave represented by $V_2 = -LvC_2$, and a transmitted wave $V_3 = LvC_3$.

Now, considering the moment when these are all at X together (corresponding elements, of course), we have the following two equations connecting the three V's:—

$$V_1 + V_2 = V_3(1 + r/Lv), \quad . \quad . \quad . \quad . \quad (56d)$$

$$C_1 + C_2 = C_3(1 + k/Sv + rk). \quad . \quad . \quad (57d)$$

The first is simply the expression of Ohm's law applied to the resistance r, and the second expresses the continuity of the current at X. [Remember that Lv and Sv are reciprocal, so that the sum of the second and third terms on the right of (57d) express the bridge current.] The equation (57d) may also be written

$$V_1 - V_2 = V_3\,(1 + k/Sv + rk), \quad . \quad . \quad . \quad (58d)$$

So that, by adding this to (56d) first, and then subtracting it, we obtain the desired ratios. Thus,

$$V_1/V_3 = 1 + r/2Lv + k/2Sv + \tfrac{1}{2}rk, \quad . \quad . \quad (59d)$$

$$V_2/V_3 = r/2Lv - k/2Sv - \tfrac{1}{2}rk, \quad . \quad . \quad . \quad (60d)$$

when written in the simplest manner. Of course the ratio V_2V_1, if wanted, is the quotient of (60d) by (59d).

We see that the reflected wave may be either of the same or of the opposite electrification to the incident; and that, in order to completely abolish the reflected wave, we require, by (60d),

$$r/Lv = k/Sv + rk, \quad . \quad . \quad . \quad . \quad . \quad (61d),$$

and that we then have, by (59d),

$$V_1V_3 = 1 + r/Lv \quad . \quad . \quad . \quad . \quad . \quad (62d)$$

simply. The reciprocal V_3/V_1 expresses the attenuation suffered by the incident wave in passing X.

The above equations are not in any way altered when we start with a real non-distortional circuit instead of an imaginary one of no resistance. But by adopting the latter course we are directed to the nearest approach to a physical explanation of the properties of the real non-distortional circuit itself. For, in the case of the circuit of no resistance we are dealing merely with progressive waves in a conservative medium, and we cannot expect to come to anything simpler than this. They simply carry their energy and all their properties forward at speed v unchanged, this speed being $(\mu c)^{-\frac{1}{2}}$, if μ be the inductivity and c the permittivity of the medium, which expression is equivalent to the other $(LS)^{-\frac{1}{2}}$, where L is the inductance and S the permittance, which is more convenient in the practical application concerned. Except in the matter of wave-length, these waves are identical with light-waves, with the peculiarity that the two (supposed) perfect conductors of our circuit prevent the waves from spreading in space generally, by guiding them definitely along the circuit. [The simplest case is that of a tubular dielectric bounded by perfect conductors, say an internal wire and an external sheath.] Now we prove by elementary principles, (Ohm's law, &c) that an inserted resistance, causing tangential dissipation of energy, produces a reflected wave of the positive kind, involving a redistribution, without loss, of the electrification on the bounding conductors; and a redistribution, with loss, of the corresponding magnetic quantity, the momentum. On the other hand, we show that a bridge causes a reflected wave of the negative kind, involving a redistribution, without loss, of the momentum; and a redistribution, with loss, of the electrification. [In speaking of redistribution, the mere translatory motion of waves is disregarded.] And by having both the bridge and the inserted resistance so proportioned as to make the loss of energy in each to be of the same amount (when small enough), we abolish the reflected wave, so that there is no redistribution, but merely attenuation produced by the resistance and bridge. This applies to any number of resistances inserted in the main circuit, each with its corresponding bridge; so that when we pack them infinitely closely together to represent continuously distributed resistance and leakage, we arrive at a real circuit, along which waves are propagated unchanged except in size. Thus any

Digitized by Google

circuit (apart from interferences) may be made non-distortional by adding a suitable amount of leakage. This amount is usually too great for practical purposes. Nor is it required. In the very important problem of long-distance telephony, employing circuits of *low* resistance (which are the only proper things to use), making the well-known ratio R/Ln of the two components of the electromagnetic impedance small, say ½ or ¼, which may be easily done without using an extravagant amount of copper, we tend naturally, by bringing the inductance into relative importance, or equivalently, reducing the importance of the factor resistance, to a state of things resembling that which obtains in the truly non-distortional circuit (independent of frequency of variations) and approximate to non-distortional transmission. These statements may be proved by an inspection of the sinusoidal solutions I have given, but it would enlarge the subject too greatly to discuss them at present. I may, however, repeat that the problem of long-distance telephony is very remote from that of a long submarine cable which can only be worked slowly, unless we should unknowingly create a parallelism by employing quite unsuitable conductors; as, for instance, was done by the Post Office a few years since when they put down conductors having a resistance of 45 ohms per mile of circuit, combined with large permittance and small inductance; and then, to make the violation of electromagnetic principles more complete, put the intermediate apparatus in sequence, so as to introduce as much additional impedance as possible. The proper place for intermediate apparatus is in bridge, removing all their impedance completely. This method was invented and introduced into the Post Office by Mr. A. W. Heaviside. It makes a wonderful difference in the capabilities of a circuit, as is now pretty well known.

The theory of tails allows us to give an intelligible physical explanation of how it comes to pass that a perfectly insulated circuit, violating the non-distortional condition completely, will yet tend to behave in a non-distortional manner to waves of great frequency, provided the circuit be of a suitable nature, as above described. For let the circuit be so long that we can get several waves into it at once, when telephoning. They divide the circuit into regions of opposite electrification, each of which may (very roughly) represent what I have termed an isolated disturbance. Every one of them has its tail, but as they are alternately of opposite kinds, their residual effect in producing distortion becomes quite small. We can see clearly that the greater the frequency the less is the distortion, unless the increased frequency should bring with it increased resistance, which is very much to be avoided, and is what renders iron wire so unsuitable for *long*-distance telephony. By this mutual cancelling of the effects of the tails, we simulate the effect of the leakage which would wholly remove distortion, even of the biggest waves, without the disadvantage of the extra attenuation thereby introduced. I am induced to make these remarks rather out of their proper place as they illustrate the importance of the non-distortional circuit from the scientific point of view, in casting light upon the obscurities of distortional circuits.

From (59d) we can get some results relating to the tails of waves in a distortional circuit. Thus, let there be n bridges in the distance x, equidistantly placed, and each of conductance Kx/n, with a corresponding resistance Rx/n in the main circuit. Let a disturbance pass from beginning to end of the length x. If σ be the attenuation at each bridge, the total attenuation of the head of the disturbance produced by all the bridges and resistances is σ^n. Now make n infinite, keeping R and K finite. The total attenuation becomes, by (59d),

$$\sigma^n = \{1 + \mathrm{R}x/2\mathrm{L}vn + \mathrm{K}x/2\mathrm{S}vn + \mathrm{RK}x^2/2n^2\}^{-n}$$
$$= \epsilon^{-\mathrm{R}x/2\mathrm{L}v} \cdot \epsilon^{-\mathrm{K}x/2\mathrm{S}v} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (63d)$$

This is therefore the attenuation of the head suffered by every element in traversing the distance x, when R and K are the resistance and the leakage-conductance in any uniform circuit.

It will now be convenient to introduce a simpler mode of expressing the exponentials. Let

$$f = \mathrm{R}/2\mathrm{L}, \quad g = \mathrm{K}/2\mathrm{S}, \quad h = f - g, \quad q = f + g, \quad (64d)$$

all four being reciprocals of time-constants. Now (63d) becomes ϵ^{-qt} simply, if $t = x/v$ be the time of the journey over the length n. If, therefore, we have initially a disturbance $\mathrm{V}_0 = \mathrm{L}v\mathrm{C}_0$ extending through the small distance a, possessing the charge $\mathrm{SV}_0 a$ and the momentum $\mathrm{LC}_0 a$, then at the time t, later, when the disturbance extends over the distance $2x$, half on each side of its initial position, being a nucleus of length a and a tail of length $2x$, the charge and momentum in the nucleus become

$$\mathrm{SV}_0 a \cdot \epsilon^{-qt} \quad \text{and} \quad \mathrm{LC}_0 a \epsilon^{-qt} \quad . \quad . \quad . \quad . \quad (65d)$$

We have next to examine to what extent the total charge has attenuated by the leakage, and the total momentum by the resistance. This we can ascertain by (59d) and (60d), applied to find the loss of electrification caused by a single bridge and of momentum by a single resistance. Those equations give

$$\frac{\mathrm{V}_2 + \mathrm{V}_3}{\mathrm{V}_1} = \frac{1 + r/2\mathrm{L}v - k/2\mathrm{S}v - rk/2}{1 + r/2\mathrm{L}v + k/2\mathrm{S}v + rk/2}, \quad . \quad (66d)$$

$$\frac{\mathrm{C}_2 + \mathrm{C}_3}{\mathrm{C}_1} = \frac{\mathrm{V}_3 - \mathrm{V}_2}{\mathrm{V}_1} = \frac{1 + k/2\mathrm{S}v + \frac{1}{2}rk - r/2\mathrm{L}v}{1 + k/2\mathrm{S}v + \frac{1}{2}rk + r/2\mathrm{L}v}. \quad . \quad (67d).$$

These fractions, multiplied into the values of the charge and momentum respectively before the splitting, give their *total* values after the splitting. We can therefore apply the previous method of equidistant resistances and bridges to ascertain the method of subsidence of the total charge and momentum in the infinitely numerous splittings that occur in a finite time when we pass to the limit and have uniform R and K. Putting $\mathrm{r} = \mathrm{R}x/n$, &c., as before, and finding the limit of the n^{th} powers of (66d) and (67d), we arrive at $\epsilon^{-\mathrm{R}t/\mathrm{L}}$ and $\epsilon^{-\mathrm{K}t/\mathrm{S}}$ respectively.

We thus see that a moving charge, no matter how it redistributes itself, subsides at the same rate as if it were at rest; for, obviously, $t\mathrm{S}/\mathrm{K}$ is the time-constant of the circuit regarded as a condenser, when uniformly charged and insulated at its terminations. It is *as if* electricity were atomic, so that we could follow the course of every particle. Thus, no matter how it moves about, it *shrinks* at the same rate as if it were at rest. Similarly as regards the momentum of the moving disturbance. Could we identify *its* elements, each would shrink in a manner independent of its translatory motions along the circuit. Notice also that the attenuation of the total charge equals the square of the attenuation of the nucleus due to leakage alone; whilst the attenuation of the total momentum equals the square of the attenuation of the nucleus due to resistance alone.

Thus, corresponding to (65d) we have—

$$\mathrm{SV}_0 a \cdot \epsilon^{-qt}(\epsilon^{-ht} - \epsilon^{-ft}) \text{ and } \mathrm{LC}_0 a \cdot \epsilon^{-ft}(\epsilon^{-ft} - \epsilon^{-qt}). \quad (68d)$$

to express the charge and momentum in the tail; since these, when added to (65d), make up the actual values otherwise found, viz., $\mathrm{SV}_0 a \cdot \epsilon^{-2qt}$ and $\mathrm{LC}_0 a \cdot \epsilon^{-2ft}$.

If $f > g$, or the resistance be in excess, the current in the tail is from head to tip, if that in the head be positive. But as time goes on, if the circuit be long enough, the head attenuates practically to nothing, leaving the big tail to work with. The region of positive current now extends from the vanishing nucleus a long way towards the middle of the tail, and in the limit the disturbance tends to become symmetrically arranged with respect to the origin from which it started as a positive wave, tailing off on both sides with the current positive on one side, and negative on the other.

But if $f < g$, or the leakage be in excess, a quite anomalous state of affairs occurs, which may be inferred from the preceeding by changing V to C, etc.

The full volutions of all tail problems (shape, growth, etc.) are contained in the following four equations. Let a charge SV_{0a} be at the origin at time $t = 0$, without any current. At time t we shall have, if $\mathrm{T} = \frac{h}{v}(x^2 - v^2t^2)^{\frac{1}{2}}$,

$$\mathrm{V} = \tfrac{1}{2}\frac{\mathrm{V}_{0a}}{v}\epsilon^{-qt}\left(h + \frac{d}{dt}\right)\mathrm{J}_0(\mathrm{T}), \quad . \quad . \quad (69d)$$

$$\mathrm{C} = \tfrac{1}{2}\frac{\mathrm{V}_{0a}}{\mathrm{L}v}\epsilon^{-qt}\left(-\frac{d}{dn}\right)\mathrm{J}_0(\mathrm{T}), \quad . \quad . \quad . \quad (70d)$$

Digitized by Google

to express the double tail or band connecting the two nuclei at its ends, which are already known. Similarly, if there be initially a current at the origin, of momentum LC_0a, without charge, then at time t we shall have

$$C = \tfrac{1}{2}\frac{C_0 a}{v}\epsilon^{-\alpha t}\left(-h + \frac{d}{dt}\right)J_0(T), \quad . \quad . \quad . \quad 71d$$

$$V = \tfrac{1}{2}\frac{C_0 a}{Sv}\epsilon^{-\alpha t}\left(-\frac{d}{dx}\right)J_0(T). \quad . \quad . \quad . \quad . \quad 72d$$

As before, put on the two nuclei at the ends. Since the J_0 function is a simple one, viz.

$$J_0(T) = 1 - \frac{T^2}{2^2} + \frac{T^4}{2^2 4^2} - \frac{T^6}{2^2 4^2 6^2} + \ldots,$$

it is quite easy to follow the changes of shape by these formulæ, except when t has become large and the nuclei small, when other formulæ may be derived from the above which will approximately suit.

(To be continued.)

TELEPHONIC COMMUNICATION BETWEEN SHIPS AT SEA.—Lieut. Bradley A. Fiske, U. S. S. "Atlanta," has an interesting paper on the above subject in the *Electrical World* of September 24th, of which the following is the most important part:—"Having carried on for many months a laborious series of experiments in the direction of electrical communication between ships, possibly my conclusions may be interesting to anyone who contemplates attacking this subject, though I am able to point out chiefly the direction in which not to work, and to tell what things it would be useless to attempt. I experimented first with a view to signalling by induction, using first a bar electro-magnet about ten feet long, whose coils were traversed by a current of somewhat more than a hundred amperes, and for a receiver a pair of Bell telephones in circuit with coils of fine wire wrapped in various ways, one coil being wrapped around a groove cut in the circumference of a soft iron wheel about thirty inches in diameter. My apparatus assumed gradually larger and larger dimensions, till at length my sending electro-magnets were the iron masts of a ship wrapped with heavy wire; and finally I made an electro-magnet of the ship itself, wrapping her fore and aft with electric light wire, and sending through the wire the current of two Gramme dynamos coupled in multiple arc. As a receiver in this case I used an iron tug about 150ft. long and 25ft. broad, wrapped with fine wire in circuit with two Bell telephones. Though the results which I obtained were encouraging, they were not sufficiently good to indicate practical value, and I concluded to thoroughly test the plan first tried on a small scale by Prof. Bell, of using the water to complete the circuit of a generator, and to use as a receiver a small wire, having its terminals in the water and in circuit with two telephones. Of course, there was no doubt that communication could be held in this way; but the thing to determine was whether it could be held with any practicable length of wire. Evidently, the longer each wire the more current could be picked up by the receiving wire; but for practical use I concluded that each ship must be limited to wires one hundred yards long, and I therefore limited myself to this length in experimenting. For a long while I got very promising results with this method, simply making and breaking the current of the dynamos according to a code; but as I increased the distance the results became uncertain. I endeavoured to produce a sufficiently rapid alteration of the Gramme currents to make a musical sound in the telephone, noticing that to a distance of more than a hundred yards I could hear a pure sound, due to the minute variations produced by collector strips passing under the brushes; but I have not as yet succeeded in doing this satisfactorily. An alternating current dynamo might solve the problem, and I hope that some investigator having control of such a dynamo will try it."

ON INDUCTION BETWEEN WIRES AND WIRES.*

BY WILLIAM HENRY PREECE, F.R.S.

Last year at Birmingham I pointed out that the electro-magnetic induction between wire and wire upon lines of telegraph extended to distances much greater than was anticipated, and that effects were observed even when the wires were separated by the breadth of England. I was not satisfied with the last experiments made in the north of England. I had reason to believe that they were vitiated by induction and conduction through the network of cross circuits and railway wires in that part of the country, so in October of last year I took the district between Gloucester and Bristol along the banks of the Severn, where it was possible to completely isolate two systems of wire separated by the River Severn for a length of fourteen miles at an average distance apart of 4·5 miles, and where any disturbing cross-inductive or conductive connection was impossible. The circuits on each side of the river could be completed by the earth or by metallic returns passing far inland, in the one case through Monmouth, and in the other cases through Stroud.

The experiments made were very numerous, but the results were almost negative. No measurable effect whatever could be detected when primary currents of ·449 ampere strength were intermittently sent by a rapid vibrator or buzzer on each side, though it was just possible to distinguish faint Morse signals. It was quite clear from subsequent experiments that we were on the extreme verge of audibility, and had we been able at the time to increase the strength of our primary current we should have heard louder effects. In fact, I have taken this experiment as a measure of the limit of audibility—a conclusion fully confirmed by subsequent results. The experiments fully justified my conviction that those reported last year as occurring between Newcastle and Carlisle were wrong.

In all the following experiments the primary currents were always of rapid frequency, producing a buzzing sound, which could be easily read when audible, if sent in the Morse code, and received on a Bell telephone.

Two squares of 1,200 yards of gutta percha covered copper wire, or 300 yards each side, and of a resistance of fifteen ohms, were placed 300 yards apart in the Porchcawl Sands in South Wales, and conversation by the Morse code was readily maintained with primary currents of ·226 ampere. Conversation by telephone was impossible. Two other similar squares were subsequently (December) suspended on scaffold poles 15ft. above corresponding squares lying on the sands, which latter were covered with water when the tide was up.

No difference whatever could be detected in the strength of the signals received by induction, whether the space were air or water, or a combination of air and water. The Irish wires on the railway were 150 yards distant from the squares, and the usual disturbance was evident on all the squares, whether under water or not.

The principal object of this experiment was an endeavour to differentiate any electro-static from the electro-magnetic inductive effect, and the conclusion drawn was that the whole phenomenon was electro-magnetic, for no electro-static effect could be obtained. No doubt with parallel wires on a line of poles, where the distance between wire and wire is far less than that between wire and earth, electro-static induction comes into play, but its effect in the cases investigated was absolutely inappreciable.

This was confirmed by further experiments made with squares of 33ft. sides, fixed 3ft. apart.

Moreover, it tends to the conclusion that the magnetic field extends uninterruptedly through the earth as it does through the air, and that if the secondary circuit had been in a coal pit it would have been equally evident.

It also accounts for the peculiar disturbance observed in submarine cables when lying near each other as described in my previous paper. I hope to have the opportunity some day

* Paper read before the British Association Meeting at Manchester, September, 1887.

Digitized by Google

of testing the limit of audibility in water. Cables, as a rule, lie too far apart for the purpose. I have made several efforts to get results on our Irish cables; but they lie apart far beyond the limit. Mr. Ash, the superintendent of the Eastern Telegraph Company at Porthcurnow, in Cornwall, joined a telephone to the ends of two cables, one terminating at Lisbon 820 miles away, the other terminating at Vigo, 620 miles away. Signals could be distinctly heard on the telephone from the Brest cable landing about half a mile away, and terminating at Penzance.

We happened during the autumn to be constructing a new trunk line carrying four copper wires from London to the coast of North Wales, and for many miles of its length in different places it ran parallel at various distances to the Great Western Railway. On Nov. 11th 1886, between Shrewsbury and Much Wenlock, 10¾ miles in length, a wire on the railway was made the primary wire, along which a periodic current of ·08 ampere was sent. Strong signals were

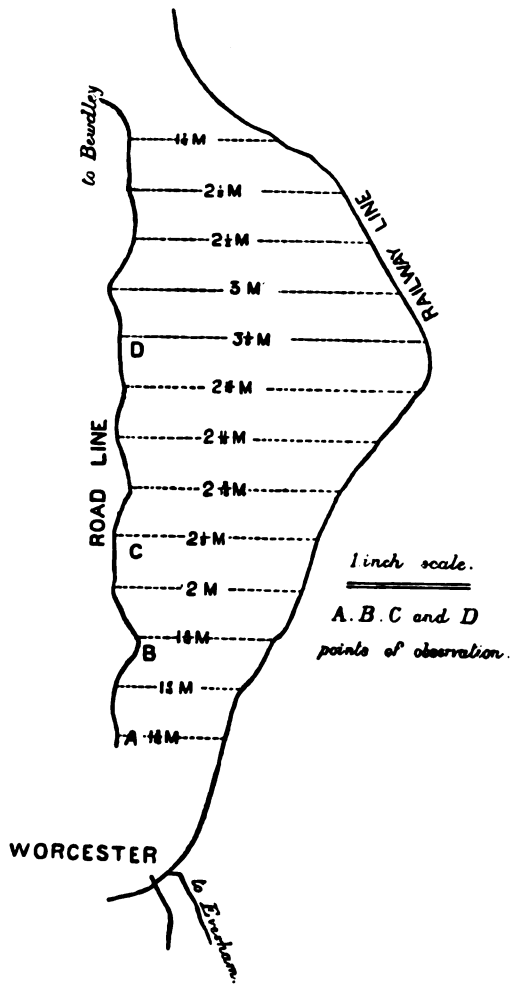

DIAGRAM A.

received on the copper wires, although they were completely isolated from any possible interference. The frizzling sound due to the ordinary induction from the mixed signals used in ordinary working were also evident, but the separating distance for 8 miles was only one quarter of a mile. Between Much Wenlock and Bewdley for a length of 12½ miles, where the separating distance averaged 1 mile 1,046 yards, the ordinary induction sounds entirely disappeared. On November 28th, 1886, similar experiments were repeated on a system of wires separated and isolated by the River Mersey for a distance of eleven miles. The primary circuit completed by the earth was on the Lancashire side. On the Cheshire side the secondary circuit was completed by a well-insulated metallic loop running inland, and measured 38½ miles in length. Morse signals were distinctly received. The separating distance was 1¼ mile. In February, 1887, the section between Worcester and Bewdley was divided into lengths, as shown in sketch Diagram A, page 25.

A wire on the railway was made the primary, the periodic current being ·12 ampere, but the results were *nil.** In no case could induction be heard between any of the points A, B, C, or D, or upon the whole length. Resort was again made to squares in a field near Cardiff, removed from all possible interference, and the standard of comparison made was the limit of audibility. This is not an absolute or a scientific standard to use, but it is practical. It depends on the variation of the human ear and the sensibility of the telephone receiver, but as the results recorded were always the conclusions of several persons, and the same telephone receiver was used in all cases, the normal ear may be assumed to have been used, and telephones do not differ much from each other when the same pattern is used. But they are much dependent on surrounding circumstances and extraneous sounds, on slight noises arising from the wind, from the rustling of the trees, from showers of rain, from passing persons or vehicles. The results of these experiments are given in the following table:—

TABLE A.

Experiments on induction at Lisvane, 2nd, 3rd, and 4th February, 1887.

Experiment.	Current in primary. C_1.	Working face of primary.	Working face of secondary. (l)	Resistance of secondary. r_2.	Limit of audibility. x.	Calculated results.
	Amperes.	ft.	ft.	Ohms.	ft.	ft.
1	·69	600	30	700	179	179
2	1·3	600	30	700	257	246
4	·69	600	60	700	585	
5	·69	600	30	700	182	
6	·69	600	30	200	641	641
7	·69	600	60	50	915	926
8	·69	600	90	76	1100	1134
9	·5	600	90	70	1373	1280

The extreme limit of audibility is derived from the Severn experiments, and is taken at 1·9016 miles, which would be the case were we operating with one mile of line and one ampere. Other conditions remaining the same,

$$x = 1{\cdot}9016\sqrt{\frac{C_1 l}{r_2}}$$

from which the sixth column is calculated.

TABLE B.

Experiments on induction, Gloucester and Berkeley, 10th April, 1887.

Experiment.	Current in primary.	Length of secondary.	Resistance of secondary, including telephone.	Results.
	Ampere.	Miles.	Ohms.	
1	1	1	85	Good.
2	·73	1	85	Somewhat lower than in No. 1.
3	·53	1	85	Slightly lower, but above limit.
4	·33	1	85	Not much distinguishable from No. 3.
5	·22	1	85	Just audible. Taken as limit.
6	·11	1	85	Not a sound.
7	·11	2	112	Faintly heard, but below limit in experiment No. 5.
8	·148	2	112	Somewhat better than No. 7, but still low.
9	·22	2	170	In these experiments the two-mile length was made equal in resistance to twice the mile length, the audible sounds being under these circumstance alike in both wires.
10	·22	1	85	
11	1 0	1	425	Current in primary increased five times, and resistance in secondary in like proportion. Audible limit reached.
12	·44	1	165	Current in primary, and resistance in secondary doubled, and audible limit again reached.
13	·85	1	335	Current in primary, and resistance of secondary increased four times. Limit of audibility again reached.

* The limit of audibility in this case was ·66 mile.

Digitized by Google

On April 10th, when the system along the banks of the Severn was again resorted to, as a primary five wires running on the Midland Railway between Gloucester and Stonehouse were bunched at each extremity, and the secondary was one of the road wires which was parallel with the railway, and at an average distance of one mile, over a length of two miles. This secondary could be joined up at will into sections of one and two miles long, the observations being made in the middle. Under these circumstances the observations detailed in Table B were taken.

Having thus obtained the conditions that determine the limit of distance across which induction is perceptible by the telephone, it became necessary to make some careful measurements so as to formulate the law that regulates the observed effects.

Let there be two wires placed parallel to each other for a length l, and at a distance d, then whenever the circuit is made in one wire a secondary current, C_2, due to electro-magnetic induction and in the reverse direction will be produced in the other wire, and when the primary circuit is broken a current in the same direction will appear in the secondary. The relation between the primary, C_1, and induced currents is given by the formula

$$C_2 = MC$$

M being a coefficient of induction depending on—

(1) The length, l.
(2) The distance, d.
(3) The resistance of the secondary circuit, r_2.
(4) The rate at which the primary current rises or falls.
(5) The condition that determines the rate at which the current rises or falls in the secondary circuit.

The following experiments were made to determine these different functions of M. The new General Post Office at St. Martin's-le-Grand is an oblong building, with four convenient corridors or galleries all round the building, along each of which perfectly insulated gutta percha covered copper wires ·050in. in diameter were suspended along the wall. The wires were 20ft. apart, and each formed a complete metallic circuit, 250 yards in length, in which any apparatus could be inserted. The building itself is a huge magnetic field in a constant state of perturbation owing to the concentration there of a thousand circuits conveying messages. The consequence was that each experimental circuit was always in a state of disturbance, rendering accurate measurements during working hours impossible and speech out of the question. Nevertheless, it was quite possible to differentiate the sound of the voice from the rest of the noises though 80ft. of space intervened. It being quite evident that no other instrument than the telephone could indicate these effects, and my object being to measure them in absolute measure two wires were suspended around one corridor at a uniform distance of 6in. apart. After obtaining reading at this distance the space was increased to 12in., and, finally, reduced to a distance of ¼in.

The primary current ·21624 ampere was obtained from a Daniell battery, and was made uniform in strength in all cases. The secondary currents were read by the throws of a Thomson galvanometer. These deflections were reproduced and measured as is done in measuring condensers. The average results of many experiments come out as follows :—

Inch.	Observed.		Calculated.
·25	·004	amperes	·004
6	·000007	,,	·000007
12	·000002	,,	·0000018

It will be seen that the law follows the inverse square of the distance, and this is fully confirmed by previous and subsequent experiments. Moreover, it is easy to show that it must be so when we can neglect the influence of the earth. It is well known, and has been fully verified in all these experiments, that the strength of the secondary current will increase directly with the strength of the primary current, and directly as the length of wire under influence within the limits of these experiments. We can thus calculate a useful standard for use.

250 yards of ·21614 ampere, at 12 inches, induced a secondary current of ·000002 ampere in a circuit of 13·27 ohms, or one mile of one ampere, at one mile distance, would induce a secondary current of ·0000000000013, or 13×10^{-13} ampere; and at two miles 3×10^{-13} ampere in wires such as were experimented with.

We can write the law thus—

$$C_2 = \frac{C_1 l}{d^2 r_2} \times M$$

I intend to repeat these experiments with care to obtain the value of the constant M in C.-G.-S. units. M = ·005.

The disturbances due to the mixed working currents on our telegraphs cannot be appreciable beyond 450ft., but those employed in distributing electric light by means of secondary generators must extend to miles unless they are neutralised by the two conductors being fixed parallel and close to each other.

I have not yet been able to make any experiments to determine satisfactorily the influence of retardation and electro-magnetic inertia on this limiting distance.

I erected two wires of iron for a mile alongside the copper wires, but was not able to get any conclusive results. It is, however, quite certain that there is a difference in the effect when the wires are of iron or of copper, and that the distance across which induction is perceptible must reach a limit of length when the resistance and capacity reduce the rate at which the currents rise and fall, and the effects must begin to diminish. Hence the disturbing effects due to short lines are more pronounced than those due to long lines.

This limit of audibility enables us to calculate the current required by a Bell telephone like that used in these experiments, to become audible. It is roughly the six ten thousand millionth of a milliampere, or in figures ·0000000000006 ampere, or 6×10^{-13} ampere.

Hence the air telegraphs used in America by Edison, Phelps and others for communication with passing trains are readily comprehended, and the distances to which disturbances are propagated between telegraphic, electric lighting, tramway circuits easily calculated. The distance through which communication can be maintained between ship and ship, between lightship and shore, between islands and the mainland, between the defenders inside and those outside a beleagursd city, becomes simply a question of calculation. I have been assisted in carrying out these experiments by Mr. J. B. Chapman, of my own office; by Mr. J. Gavey, of Cardiff, and Mr. J. R. Edwards, of Liverpool, both members of the Society of Telegraph-Engineers, and the Post Office engineers in charge of the districts affected, all of them careful and reliable experimenters

---

DISCUSSION.

Sir WILLIAM THOMSON said that a current of an ampere produced in one wire produced a certain current in the other, and he wished to know whether that was caused by the sudden stoppage of it.

Mr. PREECE said the prime currents used in all the experiments were intermittent currents of the duration of $\frac{1}{125}$th of a second.

Sir WILLIAM THOMSON: Equal time off and on?

Mr PREECE: Yes

Sir WILLIAM THOMSON distinctly understood that 6 times 10^{13} was the mean square of the current.

Mr. PREECE: That is so.

Sir WILLIAM THOMSON: There is one ampere broken 250 times per second—that is to say, there are 250 periods or breaks per second?

Mr. PREECE: Yes. I did not use reversals in this instance because they were so extremely difficult to calculate and measure, but I used simply vibrations. There were 250 distinct intermittences in the primary currents.

Sir WILLIAM THOMSON: It is an exceedingly important result, and leads the theory to very correct measurements. Was the result obtained by measurement or theory?

Mr. PREECE: By calculation. The measurements by which the calculations were made were upon the squares at a 4in., 6in., and 12in. distance, and from measurements we made to verify these at 15ft. distance, and also upon the limit of audibility obtained. Others were obtained at a distance of nearly two miles, so that the range is very great. The measurements made at 6in. and 12in. are accurate measurements of the current. They were verified by the measurements between two squares 15ft. apart, and this current is estimated from the previous measurements made and on the limit of audibility at a distance of 1·9 mile, so we know that at 1·9 mile we just lose audibility in the telephone. Just inside the distance—say 1·6 mile—we are well within the point of audibility.

Sir WILLIAM THOMSON: It is not necessary for me to say anything on the excessive importance of these researches, and the applications which

Digitized by Google

Mr. Preece has suggested for them. It seemed as if the telephone had solved the problem of telegraphy without wires, but it is exceedingly interesting and important to think that messages can be heard at a mile without any wire whatever connecting the two stations, and I think Mr. Preece deserves our best thanks for having brought this subject before us, and I am sure we all wish to hear more about it. It is a most excellent thing for science that Mr. Preece has taken advantage of the opportunities he has for experimenting on so large a scale, and I hope he will be induced to go on more and more, and give us still further results, which cannot but be valuable in practice besides being exceedingly interesting to science.

REPORT OF THE ELECTROLYSIS COMMITTEE OF THE BRITISH ASSOCIATION.*

In laying before the section this report of the Committee appointed by Sections A and B to consider the subject of Electrolysis in its physical and chemical bearings, I should first say that whereas the main lines of the report have been approved and ordered by the committee, the details and wording have not yet received final sanction, so that if the first person singular should accidentally occur in places where it ought not, it is to be understood that the real official report is that which will appear in the annual volume of the Association, and that the present is to be regarded as merely a general outline of that report.

Work has been carried on during the past year by several members of the committee; and nearly all the questions issued after the Aberdeen meeting by the secretary have been in some shape or other attacked.

The first, On the Accuracy of Ohm's Law in Electrolytes, by Prof. FitzGerald and Mr. Trouton, who reported last year and will make a further report to-day.

The second, On Conduction in Semi-Insulators, by Prof. J. J. Thomson and Mr. Newall. See the *Proceedings* of the Royal Society, No. 256, 1887.

On the third question, the Mode of Conduction of Alloys, Prof. Roberts-Austen will inform us of his experiments to-day.

Mr. Shelford Bidwell has experimented on the subject of the fourth question, concerning the Transparency of Electrolytes.

The sixth, seventh, and eighth, On the Velocity of Ions, are being worked at by the Secretary.

Concerning the ninth we have heard from Mr. J. Brown of Belfast, and on the tenth we have had a letter from Prof. Willard Gibbs.

In order to enable the members of so large a committee to work with some knowledge of what each other is doing, and also to keep up a general intercommunication and interest in the subject, it has been thought desirable and proper to spend a certain portion of the sum granted to the committee in printing and postage. Periodical circulars have been sent among the members and to a few outsiders likely to be interested, and these have been the means of drawing out one or two communications of very distinct interest and value.

It is felt that such informal reports of discussion and free circulation of provisional communications are sufficiently useful to justify the committee in continuing the practice, which was begun as an experiment, and they accordingly are asking for reappointment, with another grant of £50, of which not more than £20 is to be spent in printing and postage.

Your committee feel that the expenditure of a small sum such as this has acted, and may be expected to act, as a trigger capable of liberating in useful directions a considerable amount of energy which otherwise might have remained potential.

There are several moot points at present more or less under discussion within the committee, and I am instructed to lay them before this meeting with the object of eliciting some opinions, suggestions, or information.

First I may instance the obvious question whether electrolytic conduction and metallic conduction are sharply separated off from one another by a line of demarcation, so that no substance distinctly possessing one also possesses a trace of the other.

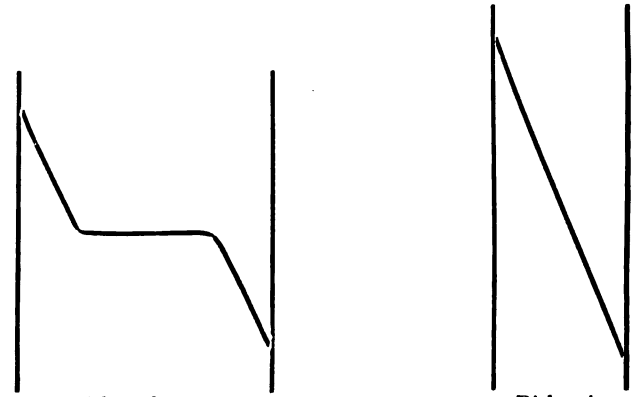
Certain contributions by von Helmholtz, among which we must reckon one on our list for to-day, lead one to believe that the conduction of ordinary electrolytes is *purely* electrolytic, and that no trace of current slips through them without carrying the atoms with it, *i.e.*, without effecting incipient decomposition.

A contribution expected from Prof. Roberts-Austen may perhaps answer the opposite question, viz., whether any ordinary metallic alloy can conduct in the least electrolytically—*i.e.*, whether a well-marked metallic alloy or quasi-compound can be in the slightest degree electrolysed by an exceedingly intense electric current.

Supposing both these questions answered in the simplest manner, viz., in the negative, there must surely remain a group of bodies on the borderland between alloys proper and electrolytes proper, among which some shading off of properties, some gradual change from wholly metallic to wholly electrolytic conduction is to be looked for. Until all such bodies as are tractable to experiment have been cautiously and strenuously examined, we are unable to say whether there is a hard and fast line between the two modes of conduction, or in what manner the gradation from one to the other occurs.

That is the first question. A second concerns the very vital point whether an electric current actually decomposes or tears asunder the molecules of a liquid through which it passes; or whether it finds a certain number of them already torn asunder or dissociated into their atoms by chemical, or at any rate non-electrical, means, and that these loose and wandering atoms thus fall an easy prey to the guiding tendency of the electric slope, and join unresistingly one or other of two processions towards either electrode, only at the last moment attempting a brief and unavailing struggle, when the electrode suddenly looms foreign and forbidding across a molecular distance of 10^{-8} centimetres.

One mode of regarding the facts is to say that across this molecular range of 10^{-8} the electrical forces *are* competent to tear atoms asunder. The E.M.F. of a volt or so can be shown by calculation to be able to do this, so that the difference between an electrolyte and a dielectric may be typified diagrammatically thus:—



The two vertical lines are electrodes, the slant or broken line represents the kind of slope of potential in the two cases respectively.

Prof. Schuster has now discovered one way in which dielectrics shade off into electrolytes; for he finds that in the neighbourhood of an electric discharge rarefied gases are able to conduct as electrolytically as liquids themselves. This discovery that the atoms of gases possess atomic charge as well as those of liquids, if confirmed by further research, is one of considerable interest.

But why do we assert the horizontality of the line of slope in the fluid? Why do physicists feel constrained to assert that no internal static electric stress is possible in the interior of a mass of fluid? The question is but the paraphrase of another. Why do we believe liquids to obey quite accurately Ohm's law for very minute forces? On this head we have direct experimental evidence by Prof. FitzGerald and Mr. Trouton, and less direct but equally conclusive evidence from von Helmholtz. Whether the evidence is perfect and thorough is doubtless a debateable point, but this much is not debateable: it is out of the question to assert that liquids obey Ohm's law and at the same time to assert the existence of a finite electrostatic stress in the interior of a fluid. In other words, however chemists are able to explain the fact of unresisting atomic processions through the liquid—whether by actual procession of individuals or by continual directed interchange—they will be rigorously driven to some form of such doctrine as soon as they accept the evidence for the accuracy of Ohm's law in electrolytic conduction.*

We all know that this doctrine of non-resistance is in some shape or another the old Williamson-Clausius hypothesis, which was based on then newly known facts concerning dissociation.

It would appear, however, that some chemists demur to the existence of a constant average of dissociation among the molecules of a liquid; and it behoves us of Section A to receive their scruples with great respect, being, we may suppose, based upon intimate familiarity with all manner of circumstances and reactions of which we physicists are only superficially cognisant.

But there are ways of picturing all that is necessary to free atomic interchange without postulating actual and constant dissociation. A *potential* dissociation will be granted, sufficient for all purposes, provided chemists admit the probability of a frequent

* As read by Dr. Oliver Lodge before the joint sitting of Sections A and B, on Saturday, September 3rd, 1887, at Manchester. Sir William Thomson in the chair.

* *Note added later.*—This sentence may have to be modified in the final Report, because at the meeting Prof. G. F. FitzGerald made some interesting observations of a controversial character respecting it: and his remarks need to be carefully considered.—O. L.

Digitized by Google

interchange of atoms among the molecules of an electrolyte going on always before any E.M.F. has been applied.

Concerning this or other mode in which electrolytic conduction takes place we may congratulate ourselves on the presence here of Prof. Quincke and Prof. Wiedemann, and we hope to hear something from them. The experiments of Dr. Gladstone, and also some unpublished ones of Prof. J. J. Thomson communicated to the committee in a letter, will probably be found to have a bearing on this point.

The question whether there is any radical distinction to be drawn between ordinary compounds and so-called molecular compounds appears to be an open one. Various physical facts lead one to suppose that whereas the ordinary forces of chemical affinity are strictly electrical there may be other non-electrical forces as well, and that such compounds as are held together by these latter forces are intractable to electrical influence. It is difficult for physicists to understand certain facts without the hypothesis of some non-electrical forces between atoms; but on such a subject as this chemists are likely to have in their hands evidence which, if at all decided and distinct, would be entitled to very great weight.

The subject of the partition of the current among different electrolytes when mixed together, and the question of the part the solvent plays in the conduction, seem scarcely suitable for discussion at the present stage, because they only require a few rigorous experiments on lines already laid down to settle them. But I may just say that whereas at a former meeting I thought I had obtained experimental evidence that the water conducted some fourth part of the current in certain solutions, I have since found that, using purer substances, and taking extreme care to avoid loss of weight by spray, which source of loss is very subtle, this evidence puts on another complexion; and at the present time I am disposed to coincide more cordially with the orthodox view, that water conducts almost as little when forming part of a solution as when existing alone. Further experimental evidence is still being obtained, however, and perhaps Mr. Shaw has something to communicate on this head.

Among several communications received by the committee from non-British philosophers is an exceedingly suggestive one by Prof. Willard Gibbs, which raises a very interesting point.

It is perfectly well known that in 1851 our present chairman, Sir William Thomson, reasoning from some experiments of Joule, taught us how to calculate the E.M.F. of a cell from thermo-chemical data,

$$E = \Sigma(J\varepsilon\theta);$$

or

$$\frac{\Sigma\theta''}{46000} \text{ volts.}$$

Strictly speaking he hedged with regard to reversible heat effects in a way equivalent to the complete equation

$$E = \Sigma(J\varepsilon\theta) - \Sigma(J\Pi) \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

Where Π_1 is the heat developed at junction 1 per unit quantity of electricity conveyed across it, Π_2 the same at the second junction, and so on.

But the value of Π, in any given case, is extremely difficult to measure, especially at metal-liquid and liquid-liquid junctions. Bouty has attempted it with but small success.

Fortunately Helmholtz has thought of applying the second law of thermodynamics to the subject, and shown that it was only necessary to know the rate at which the E.M.F. of a cell varied with temperature in order to know the sum of the Π. For, quite analogous to Prof. James Thomson's freezing point relation

$$dp\,\delta v = J\frac{dT}{T}L,$$

is the following E.M.F. relation:—

$$dE\,\delta Q = J\frac{dT}{T}\delta H,$$

or

$$\Sigma\Pi = \frac{\delta H}{\delta Q} = \frac{T\,dE}{J\,dT} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Putting the two equations together we get

$$E = JT\varepsilon\int\frac{\theta\,dT}{T^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

which we may say is certainly true.

But now Prof. Willard Gibbs suggests a novel mode of applying the second law or doctrine of entropy.

He takes into account the temperature of dissociation, or temperature at which the reaction could reversibly take place; and, calling this T_0, he writes the E.M.F. at any actual temperature T thus:—

$$E = J\theta\varepsilon\frac{T_0 - T}{T_0} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

This he gives as the complete expression; wherein, therefore, $J\theta\varepsilon$ is the chemical portion of the total E.M.F., and $J\theta\varepsilon\frac{T}{T_0}$ the thermal portion of the whole E.M.F., equal to $J\Sigma\Pi$.

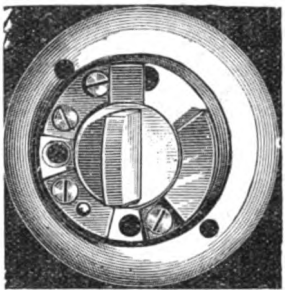
If this were a correct mode of regarding the matter, it would be of the highest interest to be able to calculate dissociation temperature in this way. Unfortunately, several of the best judges in this country have expressed to the committee their serious doubts as to the validity of thus stepping, unguided, outside the region of safe knowledge, across the great gap separating ordinary from dissociation temperatures. We wish Prof. Willard Gibbs were here to support and strengthen his position.

These are the main problems at present under discussion among the members of the committee, and with this summary of them and reference to such of to-day's papers as seem likely to contribute towards their solution the report proper may be understood to close.

I think, however, I am only expressing the feeling of the committee if I say that they view this joint sitting of Sections A and B with great interest, and with the anticipation and hope that it may be the precursor of many other such gatherings during the era of development in the borderland of chemistry and physics which in many directions they feel to be now imminent.

CHINA SWITCHES.

We have received from Messrs. Fowler, Lancaster and Co. specimens of switches which they manufacture, the external parts of which are made of china ware. These switches are made in a variety of forms and sizes, each one of which is supposed to have its special purpose. The accompanying illustration will show one of the forms, and we can say that contact is broken with great rapidity, obviating the destruction of the switch from sparking. The china ware at the back of this particular specimen, and in most of them, has a circular groove, so that when fastened to the wall none of the metal used in the lamp can—unless it is wilfully done—come into contact with the wall.



We are glad to see that china ware is coming into such extensive use for this particular apparatus in the electrical industry. It can be made in all colours, and possesses the very great advantage of being easily kept clean. These may be termed æsthetic advantages. We have not dwelt upon the matter as to the value of the material as regards its electrical properties, these being so well known. This firm also use china ware for connectors, for lamp holders, and for fuses. The workmanship of all the specimens we have seen is excellent.

AMERICAN NATIONAL ELECTRIC LIGHT ASSOCIATION: THE ELECTRIC LIGHT OUTFIT OF THE NEW CRUISERS.

BY LIEUT. J. B. MURDOCH, U.S.N.

The question of how to best install the electric lights in the new men-of-war has been considered in detail, and it seemed advisable to bring the matter before the National Electric Light Association, that the manufacturers of the country might have the problem presented to their consideration in advance of the time when they would be asked to act upon it. In conversation with managers of various companies it has been impressed on my mind that the peculiar conditions existing on shipboard are but imperfectly understood, and as a natural consequence they have not as yet been as satisfactorily met in this country as abroad. I am confident that American ingenuity and skill can fully meet our requirements, and hope that the number of dynamos, about sixty, which will be needed for the vessels already authorised by Congress, may be considered as meriting the experiments necessary for their successful installation.

I am authorised to present in a general way the views of the Bureau of Ordnance of the Navy Department, on the peculiar conditions to be met, and on the best method of meeting them.

In men-of-war the prime requirements of all kinds of apparatus are compactness and lightness. Neither of these is of any material consequence in electric light installations on shore, and both are generally

Digitized by Google

ignored. Attention has there been given mainly to the question of efficiency of conversion, and a glance at the advertising columns of any of the electrical journals shows that the maximum efficiency and best system of electric lighting is possessed by each of a dozen companies. Our conditions, so far as the dynamo is concerned, may be summarised as wishing the greatest electrical output for a given weight and bulk, and although at first thought this may seem to be essentially the same thing as efficiency of conversion, it is widely different.

The following figures of well-known American dynamos illustrate this point. The comparison is made on the basis of "watts of output per pound of dynamo." The weight, speed, and electrical output have been obtained in general from the manufacturers, and are given, of course, only approximately. In this comparison it is of course necessary to consider also the sizes and the number of revolutions, the watts per pound increasing with large machines and high velocity.

The next consideration is that of the connection of the dynamo to its engine, and a starting point is afforded in the rule that belting should never be used on a sea going vessel. Nothing so radically violates our condition of economy of space as the use of belting. When space is saved by the use of a short belt, the working conditions are comparatively unsatisfactory. Belts are liable to be thrown off by the sudden change of load to which our dynamos are subject, and become a source of danger to the attendants if the ship is rolling heavily. The adoption of fixture gearing between engine and dynamo has been suggested, and is probably practicable, but its durability on shipboard, when the motion of the vessel must cause working of the two shafts, may not be great. In the navies of Europe the practice of direct connection is universal, the dynamo shaft being coupled to that of the engine. This calls, of course, for either a great reduction of the speed of the dynamo or a corresponding increase of that of the engine. It is easy enough to procure an engine running 1,500 revolutions per minute, but it is a very different matter to find one which will govern satisfactorily at so high a speed. So far as I can ascertain there is no automatic engine manufactured in the United States capable of indicating 30 horse-power which is designed for a higher speed than 500. I have been informed, however, that some of the types now in the market could be modified so as to operate well at 500. I am not aware of any dynamo in the United States absorbing 30 horse-power, which would yield its normal output at even the higher speed. It is much easier to reduce the speed of the dynamo while preserving its electrical output than to raise the speed of the engine. Admitting the desirability of direct connection on shipboard, the problem proposed is the best method of obtaining the same outpnt in watts per pound, at speed below 500, that is now commonly obtained between 1,000 and 1,500.

The preceding figures of European dynamos, obtained in same way as those already given for American machines, and probably equally accurate, will show how this problem has been met abroad.

It is necessary to only refer incidentally to a few of the methods by which these results have been obtained. The principles are the elimination of all iron not needed for the magnetic circuits of the dynamo, and the adoption of a type in which this circuit furnishes a framework of necessary rigidity. The magnet core should be of the best wrought iron, this single condition frequently reducing the weights 25 per cent., while preserving the output. Armatures of large diameter give high perpetual velocity at low speed, and this seems to recommend the Gramme ring, a large drum armature being cumbersome. The Gramme form has another advantage for ship's use, that it can be repaired or even rewound with the facilities existing on shipboard, although I believe a Siemens winding has recently been perfected which admits of equal facility of repairs. The use of multipolar machines contributes to lightness, and the Siemens and Halske machine referred to in the preceding table has fine field-magnets inside a Gramme ring. Flattened ring armatures and multipolar magnets also give large output for the weight.

Every ship aboard which the electric light is a necessity should have two similar dynamos, that either may be used as well. At present this precaution is not observed in the navy. The lighting of the ship by incandescent lamps is under the control of the Bureau of Navigation, and the installation for this purpose consists of an ordinary plant of an engine driving a dynamo by belting. The electric search lights, two of which are furnished to each large vessel, are supplied by the Bureau of Ordnance, the installation for this purpose consisting of a Brotherton engine driving two C Grammes, connected direct on the same bed plate. In case of accident, the incandescent dynamo will not work the search lights to advantage, nor will the Grammes operate the incandescent lights well. This is of course most unsatisfactory, and the need of the service is for a dynamo which will perform either work well, and, if necessary, both at once.

Our search lights require about 50 volts and 50 amperes for ordinary work, the current being sometimes increased to 100. The lamp is operated by hand in order to fully utilise the radiation from the crater of the positive carbon. The hand lamp and Mangin Projector are in use in nearly every navy in the world for projecting a condensed train of lights to a distance. Automatic lamps do not admit of continuous adjustments as readily as the hand lamp, and are not so thoroughly under the control of the operator. In any search lights the arc may sometimes fail, and it is sometimes advisable to cut the lights out without notice. Large and sudden variations of load are thus liable to occur, and these should not affect the dynamo. It is unquestionable that incandescent lights can be worked from a series dynamo, and search lights operated by a shunt machine, but most of these proceedings are makeshifts. It is undeniable that both search lights and incandescent lights can be worked satisfactorily by a compound dynamo. I have been called upon to work all these kinds of dynamos for each purpose, and the compound dynamo works incandescent lights as well as a shunt machine, and search lights better than does the series machine supplied for the purpose. I have also worked two search lights and fifty incandescent lights simultaneously from one compound dynamo. Each search light had $\frac{3}{10}$ of an ohm dead resistance in circuit to bring the difference of potential down to about 50 volts. There is nothing new in this, but I have so frequently been asked what advantage the compound dynamo possessed that I have trespassed somewhat on the time of the Convention to give reasons for the opinion that all naval dynamos should be compound wound for a constant potential.

It is probable that many fine new vessels will require electric motors. Some of our gun carriages may be worked in this way, on account of the advantages that an electric motor offers in small weight and bulk, and in the important fact that it is so much easier to splice a broken main than to patch a leaky pipe when steam or compressed air is used for power. Electric motors will be useful for shell hoists and ammunition whips, reducing the number of men employed for these purposes. Here, also, light weight and compactness are absolutely essential, and nine-tenths of the motors in commercial use would be barred out as too heavy. A 10 horse-power motor, the largest we would probably use, should not weigh over 500lbs.

The potential at which the main should be kept must be determined from the relative importance of the three uses to which our dynamos will be put. As we are not bothered by the question of long distance transmission, we can well use a low potential for incandescent lights and motors, while search lights require only 50 volts, although it is advantageous with any dynamo to have a little dead resistance in the search light circuit. For these reasons I think 70 volts is about the best point for a compromise. This is the voltage used in the French navy, the English working at 80. If 10 search lights can be successively worked in series, the potential at the dynamo might advantageously be raised to 110, or even 120 volts. Experiments have been made to test this point, but we are not decided as yet. Should there, however, be any material advantages secured in the working of either incandescent lights or motors by the use of a high potential, the search lights could be operated with sufficient resistance to give them their proper potential.

The same requirements of small bulk and weight must control in the choice of engines. The adoption of a compound dynamo throws extra responsibility on the engine, as without constant speed the advantages of the dynamo are not apparent. American automatic engines can easily meet this demand, but most of them are too heavy, rigidity of frame being unnecessarily large masses of cast iron. 100lbs. weight per indicated horse-power, with 80lbs. steam, is a liberal allowance. In many European engines, steel and phosphor bronze have been largely used to obtain lightness.

It may be interesting to compare a few well-known dynamos as to com-

Digitized by Google

pactness, the comparison being made on watts of output per square inch of floor space.

Dynamo.	Revolutions.	Watts in External Circuits.	Watts per square inch floor space.

As illustrating the advantages of direct connection in economy of floor space and also of weights when care is taken, I have a few statistics of ship installations:—

	PLANT.	Connection.	Total Weight.	Floor Space.	Weight per 16c. Lamps.	Floor Space per 16c. Lamps.
				Sq.ft.		Sq.in.
U.S. Steamer "Chicago"	2 Edison No. 8 (200 l'ghts).. 2 Armington and Sims	Belting	16·000		40	
U.S. Steamer "Boston"	1 Brush Compound (150 lts.) 1 Straight Line	Belting	10·400		70	
U.S. Steamer "Atlanta"	1 Weston 7 W. I. (150 lights) 1 Armington and Sims	Belting	6·500	105	43	101
Steam Yacht "Alva"	1 Siemens' Compound (160 lights) ..... 1 Wilians' Engine	Direct 450 Rvs.	8·700	27	43	24
French Ironclad "Indomptable"	2 Plants each ..... 1 Multiplex Gramme(160 lts.) 1 Vertical Compound Engine	Direct 350 Rvs.	7·040	29	44	26
Torpedo Station	1 Brush No. 7 Special (100 lts.) 1 Westinghouse	Direct 700 Rvs.	4·000	17	40	25
Torpedo Station	1 Weston No. 8 Special (270 lights) ..... 1 Westinghouse Automatic .	Direct 390 Rvs.	9·300	75	42	41

The preceding show a general average of about 40lbs. dead weight of dynamo and engine for each 16-candle lamp, whether high or low speed dynamos are used. In the following, special attention has been paid to the manufacture of light and compact apparatus:—

	PLANT.	Connection.	Total Weight.	Floor Space.	Weight per 16c. Lamps.	Floor Space per 16c. Lamps.
				Sq.ft.		Sq.in.
	1 200-Light Brush Compound 1·8in. Brotherhood	Direct	5,500		27½	
Steam Yacht "Beatless"	1 Arnold Dynamo (30 lights) 1 Vertical Engine	Friction	600	6	20	29
	1 Goolden-Trotter Dynamo (75 lights)..... 1 Tower Engine	Direct	900	5½	12	11
	1 Victoria Dynamo (60 lts.) 1 Brotherhood	Direct 765 Rvs.	800	4⅞	13	11
Italian Cruiser "Dugali,"	1 Parson's Dynamo (150 lts.) 1 Parson's Steam Turbine ..	Direct 9,000 Rvs.	900	6½	6	6
	(3 plants like above.)					

It is noticeable abroad that with the type of slow speed dynamos established in the markets the system of direct connection is adopted in many isolated plants on shore. The tendency throughout Europe is to reduce the speed of dynamos, preserving the electrical output by a careful study of details. Few recent machines built abroad are designed for higher speed than 800, while an American company operating at and above 850 advertises slow speed as one of the advantages of its dynamos.

In this country the naval demand for slow speed dynamos will be comparatively small, but if it serves to introduce the type into the market I am satisfied from what has taken place in Europe that the system of direct connection will create a field for itself, as soon as the apparatus can be procured without the heavy expense attendant on special work. It recommends itself in any installation where either weight or floor space is to be economised. I believe it can be successfully utilised in lighting railway trains, especially if, in the near future, railroad companies have to furnish steam for heating purposes. Plants could be furnished small steamers and yachts in which a common installation could not find room.

There are one or two other considerations governing ships' installations. The principal is the absolute necessity of high insulation. The Bureau of Navigation has, in its recent contracts, called for an insulative resistance of 1,000 megohms per nautical mile, after twenty-four hours immersion in salt water.

That covering is also required as a protective against mechanical injury. We are so exposed to short-circuiting and corrosion from salt water that the high standard called for is most wise. All switches, junctions, and safety boxes, and in fact all parts of the circuit should be thoroughly insulated. Difficulty has been experienced from salt water running along the wires into lamp sockets short-circuiting the lamps. The insulation of the whole circuit is sometimes required to be at least 1,000 ohms for each volt at the terminals of the dynamo.

COMPANIES' MEETINGS.

The Direct Spanish Telegraph Company (Limited).

The 28th ordinary general meeting of the shareholders of this Company was held on the 30th ult. at Winchester House, Old Broad-street, under the presidency of Sir James Anderson.

The MANAGER (Mr. C. Gerhardi) read the notice convening the meeting and the minutes of the last meeting, which were signed by the Chairman as correctly entered.

The report and accounts were taken as read.

The CHAIRMAN: Gentlemen, before moving the adoption of the report I shall, as usual, make such remarks as I think may interest you. You will remember, I daresay, that we promised when the new scheme for the readjustment of our capital was carried out, that we would probably give you a dividend of 2 per cent. The report will show you that we are now in a position to declare a dividend at the rate of 2½ per cent. In the remarks I made at the last meeting I notice I held out the prospect that there might be 4 per cent. for the year, and had the traffic continued throughout as it was then we should inevitably have given you 4 per cent., but immediately after our meeting we came upon what we call the bad half-year, and the traffic went down, and continued low until about three months ago. I still hope as that was our bad half-year and this is now our good one—and we have already earned upwards of £670 more for the three months of this half-year than we did for the corresponding period of last year—that we may partly redeem our promise. We are working, as you know, at a reduced tariff, and it will interest you to know that to earn the £367 referred to in paragraph 2 of the report we have had to carry 180,000 words in excess of what we carried in the previous half-year, and the expense of earning that £367 over that of the previous half-year was £72. This half-year we are, for the three months that have gone by, £670 to the good, and I look forward, when we next meet you, to declaring a dividend that will make up at least 3 per cent. for the year. This is all we know and all we can know. It is true that the dividend is a very modest one—too modest for a submarine telegraph property. I have before remarked at these meetings, I think, that any telegraph company that can earn a dividend when forced down to a minimum tariff—that is, a tariff below which we hardly look to be forced hereafter, or, at any rate, for a very long time—any telegraph company that can pay a small dividend at such a low tariff is to be congratulated, because I think the days have gone by for high tariffs. The Press, different Governments, and rival companies are all forcing us down, and are determined that we shall not, if possible, make a living. Therefore, to get to a dividend-earning position at a tariff so much reduced is to my mind not altogether unsatisfactory. Besides, in this Direct Spanish Company we have the elements of life and growth. All the growth we have had this half-year since we became a living concern has been due to commerce. No king has died, no prince has been born, and no political complication has arisen to make our revenue greater than it would be under normal conditions. It seems to us, as far as we can examine it, to be a fair development of commercial trade. I therefore think that we are not taking too sanguine a view when we look forward to a steady growth in our revenue. At the same time I must remind you, as I am constantly reminding myself, that unless we have a good large reserve I look with grave misgivings on telegraph property; but, as you will see, we have not trenched upon the £3,000 odd we had in hand when we readjusted our capital, and we have carried forward the full reserve that we held to be necessary when we put the plan before the proprietors and the law courts. So far our revenue, such as it is, has enabled us to do that, and for the first time, I think, for five years, to pay a dividend on our ordinary shares, and that is so far very satisfactory. I do not know that the accounts call for any special remarks. It is a very small report, and it is a small revenue, and does not admit of many remarks. I hope our lines will continue in good order. If they continue in the condition they

Digitized by Google

are in now I look forward to the Direct Spanish Company becoming as good an investment as submarine telegraph companies can be. With these remarks I beg to move "That the report and accounts now presented be, and are hereby, received and adopted."

Mr. EDMUND ETLINGER seconded the motion.

Mr. DAVID LOWE asked whether there was any chance of a cable connection being made between Carthagena and Malta.

The CHAIRMAN said he did not despair of it, but whether they would connect at Carthagena or Barcelona was not quite clear.

Mr. LOWE pointed out that the Company had made a loss of £178 in their investments, which he regarded as a somewhat serious item, and suggested whether it would not be as well to redeem their debentures from the Eastern Company by giving them a bonus on those debentures.

The CHAIRMAN: What would you pay the money out of?

Mr. LOWE said he would fall back on the reserve fund of £5,000. He thought it would be to the advantage of the Company to carry out such a scheme.

The CHAIRMAN said that the question was not lost sight of by the Directors, who had another scheme in their mind for dealing with it.

Mr. JOHN NEWTON asked whether the dividend of 2½ per cent. was for the half-year or per annum.

The CHAIRMAN: Per annum.

Mr. BURT pointed out that by a clerical error in the sixth paragraph of the report the words "at the rate of" should have appeared in the preceding line to give the paragraph its full significance.

In reply to a shareholder the CHAIRMAN said that 6 per cent. was paid on the debentures.

The motion was then put and carried unanimously.

The CHAIRMAN next moved and Mr. ETLINGER seconded the following resolution:—"That the preference dividend at the rate of 10 per cent., less income-tax, and a dividend at the rate of 2½ per cent. per annum on the ordinary shares, free of income-tax, be, and are hereby, declared."

The resolution having been carried unanimously, a vote of thanks to the Chairman and Directors, proposed by Mr. D. LOWE and seconded by Mr. W. B. COCHRANE, was cordially agreed to, and the proceedings then terminated.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 30th September amounted to £3,981.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of September was 3,069, estimated to produce £2,500, against 2,675 messages, producing £2,272, in the corresponding month of last year. The traffic receipts for the month of June, estimated to produce £2,750, realised £2,929.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of September amounted to £1,990, against £1,767 for the corresponding period of last year.

DIRECT UNITED STATES CABLE COMPANY.—We are informed that the Board of this company have resolved upon the payment of an interim dividend of 2s. per share, free of income tax, being at the rate of 2 per cent. per annum, for the quarter ended 30th ult., such dividend to be payable on and after October 24 next.

EASTERN TELEGRAPH COMPANY.—This company's traffic receipts for the month of September amounted to £46,081, against £40,778 for the corresponding period of 1886.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of September amounted to £36,400, and to £30,107 in the corresponding period of 1886, showing an increase of £6,293.

GREAT NORTHERN TELEGRAPH COMPANY.—The traffic receipts of this company for September amounted to £23,600. For the period 1st January to 30th September, 1887, they amounted to £197,720. For the corresponding period in 1885 and 1886 the receipts were £217,240 and £195,560 respectively.

SUBMARINE CABLES TRUST.—Notice has been given by the Submarine Cables Trust that the balance of £1. 10s. due on the April coupon will be paid on and after 15th inst. by Messrs. Glynn, Mills and Co., of Lombard-street, between the hours of 10 a.m. and 2 p.m. After making this payment the trustees will have a small balance in hand which, with the income derivable from their investments for the next six months, will, it is estimated, be sufficient to pay the October coupon in full, on April 15, 1888. The April coupons (not those for October) must be left with the bankers five clear days before calling for payment.

WEST COAST OF AMERICA TELEGRAPH COMPANY.—The traffic receipts of this company for the month ended 30th September amounted to £4,450.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The Board of Directors of this company have declared an interim dividend of 3s. 9d. per share (free of income-tax) for the half-year ended 30th June last, being at the rate of 2½ per cent. per annum upon the Ordinary Shares and 5 per cent. per annum on the Preferred Ordinary Shares, payable on the 15th inst.—The traffic receipts of the company for the week ended September 30th, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company, were £2,944.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half-month ended 30th September are £2,368, as compared with £1,848 in the corresponding period of 1886. The June receipts, estimated at £5,706, realised £5,844.

PERSONAL.—Mr. Trotter writes to us *re* the dissolution of partnership mentioned in our issue of the 30th ult.:—I am much obliged for your notice under this head in to-day's *Electrician*. Mr. Goolden informs me that he has had several inquiries as to the probable prejudicial effect of my retirement on the future of his factory. He thinks that the feeling which prompted these inquiries will be increased by your statement that I designed the Goolden-Trotter dynamos. It has always been my endeavour since I have been a principal to give credit to whom credit is due, and on every occasion on which I have made public statements, either at meetings of the scientific societies or in the technical journals, I have been careful, where the occasion demanded it, to express my indebtedness to my staff, especially to Mr. H. W. Ravenshaw. This gentleman, who has had a thorough training both as a mechanical engineer and as an electrician, has occupied the posts of head draughtsman and assistant manager at this factory. The duties of the former post are well understood by all trained engineers, and I have every reason to expect that as he has assumed the managership of the factory, and that the rest of the draughtsmen, junior engineers, and foremen will continue without change, there is no reason, as you, Sir, observe, why under the future management on the lines already laid down, the business should not continue to command success. It is a pleasure to me to record the high esteem I feel for Mr. Ravenshaw's insight into the design of dynamos, and the instinct which he appears to have acquired through spending day after day among the details of construction and windings. Although it has not been the policy of the late firm to publish to any great extent either the methods of their manufacture or the results of their business, I think that my share of the work is sufficiently known to give weight to my expression of goodwill.

PERSONAL.—We are informed by Mr. Guy C. Fricker that he has commenced business as consulting electrical engineer at No. 12, Delahay-street, Great George-street, Westminster. Mr. Fricker mentions that he is not interested in any patents, nor will he engage in contractors' work. Taken in connection with Mr. Fricker's well-deserved reputation both as a theoretical and a thoroughly practical engineer and electrician, we anticipate that he will find considerable scope for his energies in the capacity of consulting electrical engineer.

THE GAULARD-GIBBS TRANSFORMER.—We understand that the National Company for the Distribution of Electricity by Secondary Generators, Limited (Gaulard and Gibbs system), have concluded arrangements with Messrs. Elwell-Parker (Limited), of Wolverhampton, for the manufacture of their apparatus, and that they have in consequence closed their works in Castle-street. We are also informed that Mr. Charles Moseley, whose sudden death in Manchester we regret to record elsewhere, had arranged to join the Board of the National Company.

REMOVAL.—Notice is given by the Manchester and District Edison Electric Light Company (Limited) that on and after the 6th inst. the address of the company will be 14, St. Ann's-square, and 15, Barton-square, Manchester.

NOTES.

PERSONAL.—Mr. C. H. W. Biggs has resigned the position connected with this Journal which he has held since its commencement in 1878.

THE LIGHTING OF TRIESTE.—The Municipal Council of Trieste have decided to introduce electric lighting into the town.

THE CHINESE TELEGRAPH AND TELEPHONE SCHEME.—According to yesterday's *Times* the Chinese Government have repudiated the Convention entered into by Li Hung Chang with the American Financial Syndicate.

TELEPHONE TENDERS WANTED.—Tenders are invited by a Royal order in the Madrid *Gazette* for the establishment and working of a telephone service in Salamanca. The adjudication will take place on the 29th of this month.

TENDERS FOR LIGHTING COLWYN BAY. — Tenders are asked by the Local Board for the lighting of Colwyn Bay for three years "either with gas, oil, or electric light." Information may be obtained from the Clerk to the Board, and tenders will be received up to the 18th inst.

THE USE OF SPRINGS ON TELEGRAPH WIRES.—We have received a long letter on the above subject which, however, came too late for insertion in the current issue. Communications containing drawings or photographs for insertion should be in our hands *not later* than by the first post on Wednesday morning.

COURSE OF EXPERIMENTAL LECTURES BY DR. FLEMING.—In another column will be found some particulars of a course of experimental lectures on the practical applications of electricity, which will be given by Dr. Fleming at University College on Friday, at 4 p.m. The course consists of twenty-four lectures.

THE SOCIETY OF TELEGRAPH-ENGINEERS AND ELECTRICIANS.—The first meeting of the Society of Telegraph-Engineers and Electricians for the winter session will be held on 10th November, when a paper will be read "On Deep Sea Soundings in Connection with Submarine Telegraphy," by Mr. E. Stallibrass, F.R.G.S., member.

THE INTERNATIONAL SOCIETY OF ELECTRICIANS AND THE PARIS EXHIBITION OF 1889.—M. Berger, the Director-General of the forthcoming Paris Exhibition has addressed a letter to the President of the International Society of Electricians, requesting the good offices of that body in acting as intermediary for the assistance of foreign exhibitors in the electrical section of the Exhibition.

CHESTERFIELD.—The National Telephone Company are making arrangements for opening a telephone exchange in this town. Chesterfield is at this moment probably the most important town in the country which still remains without telephonic communication. A trunk wire will be run to Nottingham and Sheffield, and not less than 10,000 firms will be brought within hail of the local exchange.

"THE RADIAL DISTRIBUTION OF CURRENTS IN WIRES."—We commend the paper under the above title, which will be found in another column, to the attention of all students who are engaged in grappling with the difficulties of alternating currents. The paper is of a non-mathematical character, and will be found very helpful in giving clearness of conception upon a particular point which is but little understood.

"MODERN VIEWS OF ELECTRICITY."—We would call the attention of our readers to a most valuable and interesting paper under the above title in last week's *Nature* from the pen of Dr. Oliver Lodge. The paper is the revision and expansion of a lecture delivered by Dr. Lodge partly at the London Institution, on January 1st, 1885, and partly at the Midland Institute, Birmingham, November 15th, 1886, but not hitherto published.

THE WOODWARD SECONDARY BATTERY.—A company has recently commenced operations in Michigan for the manufacture of a secondary battery, of which the positive plates are made in the following way:—Molten lead is poured upon common salt or other suitable soluble substance, and the two substances are intimately mixed together. After cooling the salt is washed out, and a porous plate is left, which is filled with peroxide.

TRIAL OF THE ELIESON ELECTRIC BOAT.—Elieson's electric boat, "The Countess," of which we gave a description some months ago, received a second and successful trial on Wednesday last, in the Albert Dock. We may repeat that this boat is 90ft. in length, the screw is 3ft. 6in. in diameter, with a pitch of 5ft. 6in., and runs at 200 revolutions per minute. "The Countess" is thus the largest boat to which electrical propulsion has yet been applied.

TELEGRAPH LINES TO PARIS.—There are in all 43 telegraph lines and cables by which Paris is placed in communication with the other European States. Of these there are 12 lines to this country, 10 to Germany, 3 to Austria, 4 to Belgium, 1 to Denmark, 1 to Spain, 2 to Holland, 6 to Italy, and 4 to Switzerland. There are only ten cities and towns in France which possess more than one line to Paris. These are as follows:—6 to Marseilles, 4 to Bordeaux and Lyons, 3 to Lille, Havre, Brest, and Toulouse, 2 to Amiens, Montpelier, and Nantes.

THE "INTRINSIC LIGHT" OF SOURCES OF ILLUMINATION.—M. D. Monnier defines the intrinsic light (*éclat intrinsique*) of a lamp as the ratio of the photometric power to the illuminating surface. This obviously depends very largely upon the temperature of the source of light. The following figures are given as the intrinsic light of certain lamps:—

Argand burner	0·3	candle per	sq. cm.
Siemens' regenerative burners	0·6	,,	,,
Incandescent lamp.....	30	,,	,,
Arc lamp	480	,,	,,

THE BALTIMORE AND OHIO TELEGRAPH SYSTEM.—The purchase of the Baltimore and Ohio telegraph system by the Western Union Company is at length an accomplished fact. This transaction goes a long way towards giving the Western Union Company the monopoly of the telegraph system of the United States. It is said that the sum paid down amounts to about £800,000, but in addition to this it is agreed to pay a rental which, if capitalised, would amount to very nearly another million sterling. The Western Union directors have authorised the issue of $5,000,000 of stock to provide the necessary funds.

TRAIN LIGHTING EXTRAORDINARY.—We have seldom seen a more remarkable or original notion put forward in a responsible quarter than that contained in a French specification filed by *La Société pour le transport de la force par l'Electricité*, as a method of lighting railway carriages by electricity. This is the company of which M. Marcel Deprez forms so distinguished an ornament. The proposal is to place a small wind-

Digitized by Google

mill upon the roof of each carriage, and so to provide motive power for the usual paraphernalia of dynamos, secondary batteries, and glow lamps. As to the prospects of success of this scheme, while of course we shall hope for the best, yet we are prepared—we may say *fully* prepared—for the worst.

THE AMERICAN INSTITUTE ELECTRICAL EXHIBITION.—The Annual Exhibition of the American Institute was opened in New York on the 28th September. Most of the leading manufacturing electrical firms in America are more or less extensively represented. The building is lit by 100 arc lamps of the Ball Electric Company, and 500 incandescent lamps on the Mather system. The historical section has been greatly enriched by loans from the Franklin Institute, the Stevens Institute, and a number of private individuals, and is a large and highly valuable collection. It includes Franklin's original friction electric machine, a piece of the first Morse message, an old Morse printer, Prof. Farmer's first self-exciting dynamo machine, and motors of curious construction.

PERSONAL.—We have much pleasure in inserting the following communication from Messrs. Laing, Wharton and Down. A full account of Mr. Pope's gallant deeds appeared in our columns at the time:—"Sir: You will remember that on the 14th of July our engineer, Mr. Gilbert C. Pope, di-played great courage at Waterford in saving the life of Mr. D. Keogh, and again on the 30th in bringing to shore the body of Mr. Baldwin. These gallant acts were duly represented by us to the Royal Humane Society, and we have now the pleasing task of forwarding to Mr. Pope the certificate and medal which have been awarded to him. We think this may be of interest to some of your readers, and trusting you will find space to record it, we are, yours, &c., Laing, Wharton and Down."

ELECTRO-PLATING WITH ALUMINIUM.—In the *Jewellers' Journal* the following recipe for electro-plating with aluminium is given by Herman Reinbold:—"Fifty parts of alum, $AlK(SO_4)_2 + 12H_2O$ are dissolved in 300 parts of water, and to this 10 parts of chloride of alumina (Al_2Cl_6) are added, heated to 200deg. and cooled, whereupon 39 parts of cyanide of potassium are added. The object to be plated has to be cleaned, and to be absolutely free from grease in any form, whereupon it is suspended in the bath over the electro-positive electrode, the plate of metallic aluminium to be suspended on the negative pole. The electric current ought to be weak. The plating when polished will be found to be equal to the best silver plating, having the advantage of not being oxidised or getting black when brought into contact with sulphurous vapours, which would make it especially valuable for plating spoons and tableware."

WESTON-SUPER-MARE.—A local journal has the following paragraph:—"The unanimous expression of opinion of the meeting held at the Victorial Hall last week in favour of introducing the electric light into Weston-super-Mare has induced initiatory steps for the formation of a local company for supplying the light. It is hoped that Mr. Massingham, of Bath (the originator and managing director of the Taunton Electric Lighting Company), may be induced to accept the position of managing director of the Weston Company, as such an arrangement would relieve the local promoters of a large amount of responsibility, and help to insure the technical and financial success of the undertaking. We understand that the accounts of the Taunton Company for six months ended 30th June last, after making every allowance for depreciation, &c., show a dividend at the rate of 6 per cent. per annum upon the whole of the paid-up share capital."

THE PROJECTED IMPERIAL TRANSPACIFIC CABLE.—A Canadian journal states that the Dominion Government has received an intimation from the Imperial authorities that the British Government cannot undertake the cost of a special survey of the route of the proposed Transpacific cable between British Columbia and New Zealand and Australia unless some guarantee is given that the line will actually be laid. Under these circumstances Mr. Sandford Fleming, who may be looked upon as the father of the intercolonial cable scheme, has suggested to the Hon. Mr. Foster, Minister of Marine and Finance, that the Colonies themselves should undertake the cost of survey, and he proposes that Canada's contribution thereto should be the loan of a vessel. Mr. Foster is favourably impressed with the proposal, and will at once lay the matter before his colleagues. Should the Government decide on accepting the proposal, communications will at once be opened with the different Australian Governments.

TWISTED JOINTS IN TELEPHONE LINES.—It will probably surprise most telegraph and telephone engineers in this country to learn that in the States a distinct preference is now expressed for a twisted over a soldered joint. When the Long-Distance Telephone line between New York and Philadelphia was first projected experiments were carried out in order to test the value of the MacIntire as compared with the Britannia joint. The MacIntire joint is thus briefly described:—"These connectors are two little tubes soldered together, and you run the wires in and then twist them." For iron wires the tubes are made of iron, and for copper wires of copper, so as to avoid galvanic action. The tests made by the Long-Distance Telephone Company are said to have proved that this joint takes the same breaking strain as any other portion of the line, while the Britannia joint breaks at a tension 15 or 20 per cent. lower. We confess to finding some difficulty in swallowing this story, though it comes on excellent authority. We should like to know whether any of our readers are in a position to endorse the statement.

THE "TRANSACTIONS" OF THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.—The American Institute of Electrical Engineers has lately determined that the *Transactions* of each monthly meeting shall be printed and published separately as soon as possible after the meeting has been held, instead of being withheld, as hitherto, for an annual volume. This change will, we are sure, tend to increase the usefulness and importance of the American Institute. The first number issued under the new *régime* (forming the commencement of the fifth annual volume) has just reached our hands. It contains a valuable paper, by Mr. A. Reckenzaun, "On Electric Street Cars; with Special Reference to Method of Gearing." Mr. Reckenzaun dealt in turn with each of the following kinds of gear:—Steel spiral cords, chain gearing, conical discs and chains, belting, spur gearing, friction gear, and the worm and wheel gear. Mr. Reckenzaun has apparently seen no reason to modify his preference for the latter form of gear, of which he has long been the champion. If possible we shall take an early opportunity to reprint this paper.

AGGLOMERATE LECLANCHÉS.—MM. Bender and Francken give the following recipe for making agglomerate Leclanché cells:—

Manganese peroxide	40 per cent.
Graphite	44 „ „
Gas tar	9 „ „
Sulphur	0·6 „ „
Water	6·4 „ „

These substances, says the *Révue Scientifique*, are reduced to a

Digitized by Google

fine powder—gas tar and water apparently included—they are then carefully mixed, placed in a mould and strongly compressed. The mixture is then gradually raised to a temperature of 350deg. C., which not only evaporates the water but also drives off the volatile elements of the gas tar. This result is aided by the presence of the sulphur; a portion of the sulphur combines with the gases derived from the tar and disappears, while the remainder is said to combine with the solid ingredients, producing an unassailable compound, by a transformation analogous to that of the vulcanisation of india rubber.

THE ALLEGED EXTRAORDINARY OUTPUT OF MOTOR-GENERATORS.—If any of our readers are not perfectly clear as to the definition of a "motor-generator," we beg to refer them to a further note and also to an article which will be found on another page. Meanwhile we wish to call attention to the following statement which is given by the *Electrical Review* of New York, apparently on the authority of the inventor. Assuming the statement, to be correct, it appears that "a 100-light induction coil transformer [of ring shape] for alternating currents, costing $200, when placed in a field costing $100, and used as a motor-generator, will run 1,000 lights, *and the output is limited only by Foucault currents.*" We all know that a rotating coil may be used at a higher current density than if stationary, but that the difference is in the ratio of 10 to 1 will, we imagine, be a revelation to most of our readers. It is still more startling to learn that the output is limited only by Foucault currents. The only reasonable suggestion that we can offer is that the writer confines himself to the consideration of the section of the iron core, and assumes that the diameter of the wire is capable of indefinite increase. We shall await further information with considerable interest.

CONTINUOUS CURRENT TRANSFORMERS OR MOTOR GENERATORS.—The opinion has been hazarded that the distribution of electrical energy will in the long future be carried by means of continuous current transformers, or (as they are now called in America) motor-generators—always provided that our ideas are not revolutionised meanwhile by some overwhelmingly novel departure. However this may be, it is highly satisfactory to know that this method of distribution is at length to be put to the test. When it is added that the scheme is promoted in New York by T. A. Edison, it is a sufficient guarantee that the system will obtain a trial under most favourable conditions for the development of its latent capabilities. A full and illustrated description of the several patents under which Edison is working will be found in another column. We reserve a critical discussion of this system for another issue. Moreover, by one of those remarkable coincidences which seem to be the peculiar characteristic of electrical industry, it so happens that we have just received MSS. and drawings, giving a complete account of a system running on very similar lines which has been worked out on this side of the Atlantic. Meanwhile, what are Messrs. Paris and Scott doing?

THE PROJECTED FRENCH CABLE TO THE ANTILLES.—The *Bulletin des Société de l'Electricité* gives currency to the statement that M. d'Ockza has succeeded in forming a syndicate with a capital of 20 million francs, in order to carry out the long-talked-of scheme for laying a cable to the Antilles. It will be recollected that in the spring of the present year the Chamber of Deputies definitely refused to grant a subvention for this undertaking. M. d'Ockza and his friends wish it, however, to be understood that they are sufficiently enthusiastic to face the financial risks involved in the scheme even without the aid of a Government subvention. It is stated, moreover, that the core of the cable is to be manufactured by the Société Générale des Téléphons, at Bezons, but that it is to be armoured in this country at Henley's Telegraph Works. It need hardly be said that this will prove not only a very expensive but also a very risky method of getting the cable made. The *Bulletin* hints that the scheme is probably intended to remain on paper, and that it has been floated in part for the encouragement of the shareholders of the Banque-Franco-Egyptienne, who are largely concerned with the affairs of the Société Générale des Téléphons. We give these rumours for as much as they may be worth.

THE U. S. GOVERNMENT VERSUS THE AMERICAN BELL TELEPHONE COMPANY.—The celebrated action in which the United States Government applied to have the Bell Telephone patents cancelled came before the Court at Boston on the 26th September, and resulted once more in victory for the Bell interest. On behalf of the Government it was prayed that the Court would decree that the said patents are and have been since the date of sealing and delivery null and void; that they were wrongfully procured to be issued by means of fraud, false suggestion, concealment and wrong on the part of Mr. Bell, and that the American Bell Telephone Company may be perpetually enjoined from making use of any right or claim under said letters patent, or from alleging the same in any court within the United States as evidence of any grant or right conferred on Mr. Bell. The Court arrived at the conclusion, first, that no provision existed in the Statutory law enabling it to decree the cancelling of a patent, and it was further of opinion that the Government had exceeded its powers in making such application. It is reported, however, that the case will be carried to the Supreme Courts. Should the Supreme Court sustain the present decision, it would not be surprising if the Telephone Company brought an action against the Government to recover damages. One peculiarity of American lawsuits is that one never knows where to find them. This case, for instance, was first heard of in the courts at Memphis; it next turned up at Colombus, Ohio, and is now decided at Boston.

THE HEATING OF POINTS BY ELECTRIC DISCHARGE.—The French Academy has of late had very little electrical matter under discussion; the last number of the *Comptes Rendus* contains, however, a couple of electrical papers. One of these is of a mathematical character, dealing with the graduation of the quadrant electrometer, by MM. P. Ledeboer and G. Maneuvrier. The second is a note of M. Semmola on the heating of points by the electric discharge. It seems doubtful whether very much importance can be attached to the question, but however this may be there can be no doubt as to the ingenuity of the method by which it was investigated. M. Semmola took a pointed metallic stem, of which one half consisted of antimony and the other of bismuth, the two halves being joined longitudinally. The point being attached to the conductor of an electro-static machine, the two metals were also connected with a low resistance galvanometer. When the machine is placed in action a thermo-electric E.M.F. is generated, which is, of course, proportional to the rise in temperature of the point compared with the base of the stem. The most interesting result thus obtained was a proof of the fact that the discharge of negative electricity produces greater heat than a positive discharge. An actual spark discharge, even when nearly continuous, produces much less heat than the glow discharge. The "electric wind" which issues from a point is itself above the temperature of the air. The author suggests that a compound point of this character might sometimes be

Digitized by Google

used to advantage in exploring the electrical condition of the atmosphere.

THE PHYSICS OF THE SUN.—The October number of the *Phil. Mag.* contains three separate articles devoted to the physics of the sun. If any apology be thought necessary for calling attention in these columns to a subject of such profound interest, it may be sufficient to recall the fact that but for the agency of electricity in obtaining comparison spectra it would be impossible to pursue the inquiry as to the presence of the terrestial elements in the solar sphere. The first of these papers is a record of the results of a new research undertaken at Harvard University by Prof. J. Trowbridge and Mr. C. C. Hutchins with a view to the verification of Prof. Draper's discovery (in 1877) of the presence of oxygen in the sun. This discovery has never until now been seriously called in question. Prof. Trowbridge was, however, enabled to bring to bear far more powerful appliances, and in the result he is led to the conclusion that there is no evidence of the existence of oxygen in the sun. The comparison spectra was obtained by means of a spark discharge in air, furnished by the secondary coils of three large induction coils, in which the primaries were traversed by an alternating current. Great difficulties were experienced from the heat developed. The electrodes consisted of two stout aluminium rods. The second paper is devoted to the question of the existence of carbon in the sun, and to this an affirmative answer is returned. These experiments, which were also carried out at Harvard College, were made by means of the ordinary arc between electric light carbons. The authors were led to conclude that at the point of the sun's atmosphere, where carbon is volatilised, the temperature of the sun approximates to that of the voltaic arc. The third paper, by Prof. A. Grunwald, is on the "Dissociation of Hydrogen and Oxygen in the Sun's Atmosphere."

THE TELEPHONE SIREN.—Dr. Karsten writing in the *Elektrotechnische Zeitschrift* describes an instrument under the name of the telephone siren which consists of a disc on which a number of bar magnets are arranged radially with their similar poles adjacent. By means of a clockwork driven by weights this disc is made to revolve in front of a fixed iron core upon which a coil of wire is wound. A telephone receiver is placed in connection with this coil, and on rotating the disc the induced currents set up a clear and distinct note in the receiver. The pitch of the note may obviously be changed either by altering the speed of rotation or by varying the number or the arrangement of the magnets. If the inner poles are arranged N, N, N, &c., a certain note is produced at a certain speed; with the arrangement N, S, N, S, &c., the note is an octave lower; with the arrangement N, N, S, N, N, S, three tones are simultaneously heard. The highest of these is given as being the same as in the first arrangement, the next is an octave deeper, and the lowest is a fourth to this octave. When a sufficiently powerful motor is used to revolve the disc, tones of equal loudness throughout can be produced, and when compared with those emitted by other instruments the well-known beats are clearly audible. The telephone siren can therefore be used to determine the vibration-frequency of any note, as well as to prove the principle of interference caused by vibrations whose wave-lengths are opposite in phase. The instrument is also applicable to the telephonic determination of electrical resistances in which equality of resistances in a Wheatstone bridge is detected by an absence of sound in the telephone. This mode of testing is often rendered uncertain by extraneous disturbing sounds, but the clearness of tone of the telephone siren can always be distinguished from superposed sounds from other sources.

THE FIRE OFFICE RULES.—We are extremely glad to see that the vexed question of fire office rules which threatened to work such confusion in the electric lighting industry has been practically settled—and that in the common sense manner which might have been expected when the subject was taken in hand by business men. The efficacy of the Phœnix rules themselves has never been brought into question. The only plea raised on the side of the malcontents was that one or two offices did not care for the title page of the pamphlet. Two or three weeks ago a leading office placed themselves in communication with the Phœnix, with the view of settling once for all any objection that might ever arise on this score, and its suggestions were accepted. They were simply this—that the Phœnix rules be issued in two separate covers, one with the well-known title, the other with the title altered to "The Fire Office Rules"—this last form to be used by any persons who were sensitive as to the former title. We have received a copy of the latter issue together with the 10th edition (second issue) of the Phœnix rules, which, as already stated, are identical save for the covers. With regard to any particular rule itself, it is well known that Mr. Heaphy, on behalf of the interests he represents, is perfectly willing to give every attention to such suggested modifications as may be made at any time, provided that such alteration does not injuriously affect the insurance interest. The Phœnix Fire Office has never shown the slightest desire to impose any harsh or unjust restrictions, but, on the contrary, to give the freest possible scope to electric light industry, in the fullest manner compatible with safety. In this matter we can only repeat what we have already said, that the electrical interests are in England placed in a far more favourable situation than in any other country. It may now be hoped that this agitation, which cannot be otherwise than injurious, may be allowed to die a natural death.

EFFECTS OF LIGHTNING ON RAILWAY SIGNALS.—The *American Railroad Gazette* writes on the above subject as follows:—"The effect of lightning on electrical apparatus of all sorts is a subject on which accurate data seem rather scarce, and its effect on railroad signals especially is a point on which more light is needed. A cardinal principle in signals which are in any degree automatic is that they shall show danger in the event of any derangement, and numberless ingenious devices have been invented to provide against the possibility of a signal standing at safety when it has not been intelligently put in that position; but lightning is such a lawless element, and may influence electrical apparatus in so many different ways that the counteracting of the harm it may do is not an easy task. It may make a ground connection, and thus allow a circuit to appear all right when it is not, being closed at one end and open (without battery) at the other. It may melt fixtures so as to permanently hold a signal in the position it is in at the moment; and again it may charge a wire with a current that will actuate the electromagnets and work the signals when the signal man has taken no action whatever. While the chances of a signal being held any length of time in the safety position from the effects of lightning alone are very small, and while it is probable that nearly or quite all danger in this respect can be guarded against by cautionary instructions to the attendants, it is nevertheless well to make note of all peculiarities noticed, that experience may be compared. In a recent thunderstorm at Palmer, Mass., the electric locks on the interlocking machine at the crossing of the Boston and Albany and New Londo

Digitized by Google

Northern were alternately locked and unlocked several times by atmospheric electricity in the rails at and near the crossing. The storm also showed one of the disadvantages of underground wires. A lightning shock generally runs along a wire until it encounters more than ordinary resistance and then melts the conductor. An underground wire is more likely to have unequally corroded sections than an aerial one, and so furnishes first class opportunities for the lightning to fuse and part it, where, in the case of a wire hung in the air, the resistance and damage would more likely occur in the office connections or apparatus."

SHOCKS FROM DYNAMO MACHINES.—We have recently published from American sources several contributions to our knowledge of this important though painful subject. The following is an extract from a letter addressed by Mr. C. Smith, of Pittsburg, to our esteemed contemporary the *Western Electrician* of Chicago. Mr. Smith is criticising a paper read before the Chicago Electric Club by Mr. C. C. Haskins. He says :—"As Mr. Haskins wishes to know 'full particulars' as to the shocks that I have received, and of which I spoke at Boston, I will give them to him, and he can repeat the experiments whenever he likes and compare results. Let him take a 30-light Brush machine, running with a full load of lamps, take hold of the bare wire in one hand and a brass coupling in the other, and pull them apart. (I did this, of course, not knowing that the current was on the wire.) Result: A couple of burns on the hands, a knock down off a step ladder, and blue spots and general stiffness and soreness in both arms and across the chest for a week afterwards. Secondly, let him stand with wet feet on the wire running from the negative terminal of a Thomson-Houston 20-light machine, and hold on to the positive terminal while somebody else—with the idea of releasing him—opens the line. Result: Burnt hands and blistered feet. Thirdly, let him come into one of our alternate current stations where the bars of the switch-board are of bare copper about one foot apart, with a difference of potential between them of 1,000 volts, and let him, while coupling in a new circuit, place one hand on each bar. Result: Two little burns, about the size of pin heads, on each hand. After these experiments he will be in a position to criticise. Mr. Haskins showed in one of his experiments that he got a spark and a shock from the extra current from a magnet with six Leclanché cells. If he will call at our station in Pittsburg, I should be happy to show him the breaking of an alternate current of 65 amperes at 1,000 volts (the full current of one of our 1,300-light dynamos), with no more spark than would be seen in the breaking of a direct current of two amperes at 100 volts, and in about three weeks I expect to be able to show him 130 amperes at 1,000 volts (or 2,500 lights) broken with no greater spark. Mr. Haskins does not seem to have at all understood the purport of my remarks, which was not that the 1,000-volt alternate current is harmless, but that the 1,000-volt alternate current is very much less dangerous than the 1,000-volt direct current, and I would call his attention to the fact that his spark and shock from the six cells of battery and magnet is a direct current, and not an alternate current, and may easily be of many hundred volts."

PROF. EWING ON THE PRESENT POSITION AND PROSPECTS OF THE ELECTRIC LIGHTING INDUSTRY.—On Monday last Prof. Ewing gave the first of a course of ten popular lectures on electric lighting in the Engineering Class Room of University College, Dundee, the subject of the introductory lecture being "The Present Position and Prospects of the Electric Lighting Industry." After some preliminary remarks the lecturer went on to speak of the progress in electric lighting during the last five years, under the several heads of production of electricity, storage, distribution, and lamps. The apparatus was now vastly more efficient and very much cheaper. Dr. Fleming had lately shown that the first cost of a large dynamo was then about £2 per lamp, now it was only 7s. Lamps were now more durable. Storage batteries are trustworthy and permanent. By transformers it had become possible to convey electric energy in the form of a current of small quantity at great pressure, thereby requiring only small conductors, and then convert that into currents of large quantity and low pressure suitable for ordinary domestic use. By this means the problem of economically distributing electricity for incandescent lighting from a central station was in a fair way to be solved, and in the last year Mr. Westinghouse had put up 27 such stations. The electric meter of Prof. Forbes, made public only last month, would serve to tell how much electricity each householder was consuming, just as a gas meter did for gas. Apart from the question of general distribution from central stations, the electric light was now an assured success as the illuminant of large open spaces, of ships, of exhibitions, of theatres, of the country mansions of the rich, and of mills and factories. The question that determined the use of the electric light was almost wholly a question of cost. Was it or was it not cheaper than gas? To that question it was now possible to give a definite answer. Supposing, as was often the case in Dundee mills, the power required could be taken from the mill engine, then wherever night work was to be done electric lighting by incandescent lamp was unquestionably cheaper than gas. If there was only day work—that is, if light was required only for a few hours in the early morning and the late afternoon of the winter months—then gas and electricity ran almost neck and neck as regards cost; but if light was wanted for anything like a thousand hours in the year then electricity was distinctly cheaper, even allowing in the most liberal way for interest and depreciation on the permanent plant, as well as for the cost of lamp renewals, coal, oil, &c. More than two years ago he pointed this out in a lecture in Dundee as the result of a calculation, and shortly after he had the opportunity of making practical proof in mills in the Dundee district where he had been consulted professionally regarding the electric light. In one of these factories the calender was lighted by electricity, and was used occasionally for night work. After two years' use the manager had given him figures for the actual cost. For 1,200 hours' work during one year the whole cost of lighting by electricity, including interest and depreciation, was under £50. The same area had formerly been lighted by gas, and the gas bill for the same number of hours' work had been £82. If the plant had been of the most modern kind the difference would have been still greater in favour of electricity. In another case, in the underground warehouse of a Dundee mill, where they had formerly made shift to work with the dimmest light for fear of fire, the electric light had been introduced under his supervision, and the results had been very interesting. He recommended that as a brilliant light was not wanted the lamps should be worked, for the sake of economy, at a low degree of incandescence. This had been done, and some of the lamps, burning every working day for ten hours, had lasted for more than 7,000 hours. Their average life had been 5,500 hours. In conclusion, the lecturer said there were many signs that the electric light industry, after a long time of great depression—during which, however, the engineers had not been idle—was about to enter on a period of rapid growth.

THE RISE AND PROGRESS OF TELEPHONY IN THE UNITED KINGDOM.

(Continued from page 413.)

Having related in the last chapter how it came to pass that the plea of premature disclosure (at Glasgow and in the columns of the press) of the principle of the Bell telephone resulted in a judicial decision in favour of the holders of the patent, we arrive now at the second chief line of the defence adopted by Messrs. Harrison, Cox-Walker and Co. In this it was sought to be shown that the invention of the telephone had been anticipated by Philipp Reis. It will better accord with the method of our brief historical survey if we deem it unnecessary, in the first instance, to confine our account to the evidence actually produced at the trial. By dint of availing ourselves of the subsequent labours of Prof. Silvanus Thompson, we shall be enabled to present a clearer account of what Reis actually accomplished, and thus to do justice to the memory of a remarkable and highly gifted man, whose scientific fame should in no degree be affected by the fact that his researches did not lead to immediate practical results. The limits of the case as presented in the English courts, and the points upon which the judicial decision was subsequently based will be indicated in due course.

In the year 1860 Philipp Reis, at that time a schoolmaster at Friedrichsdorf, commenced his researches on the transmission of speech by electricity. In a letter* to Professor W. F. Barrett, Dr. Messel, a former pupil of Reis, thus describes the primitive apparatus which the inventor first con-

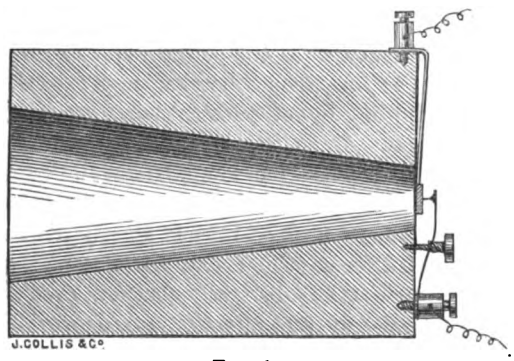

FIG. 1.

structed. "The transmitting instrument was a bung of a beer-barrel hollowed out, and a cone formed in this way was closed with the skin of a German sausage, which did service as a membrane. To this was fixed with a drop of sealing-wax a little strip of platinum corresponding to the hammer of the ear, and which closed or opened the electric circuits precisely as in the instruments of a later date." In Prof. Silvanus Thompson's work no less than ten different and successive types of the Reis transmitter are illustrated and described, but as to their essential parts they are every one practically identical with the original instrument described by Dr. Messel. By the kind permission of the author we are enabled to reproduce some of the illustrations from the work in question. Fig. 1 shows the form of Reis transmitter which has been called the "hollow cube." The following is the original description† by Prof. Böttger, which appeared in the *Polytechnische Notezblatt* in the spring of 1863:—"A little light box—a sort of hollow cube of wood—has a large opening at its front side and a small one at the back of the opposite side. The latter is closed with a very fine membrane which is strained stiff. A narrow springy strip of platinum foil, fixed at its outer part to the wood, touches the membrane at its middle; a second platinum strip is fastened by one of its ends to the wood at another spot, and bears at its other end a fine horizontal spike, which touches the other horizontal spike where it lies on the membrane."

A great controversy has raged around the question as to the precise mode of action of these transmitters of Reis, whether by actual interruption of the circuit or by variation of contact resistance; it has even been denied that they were capable of acting at all in the sense of transmitting articulate speech. On the latter point, however, the testimony adduced by Prof. Thompson seems to us conclusive, but we are equally inclined to believe that the action of the Reis transmitter was "microphonic" in character, being due to the variation of resistance of a loose contact. We base this conclusion upon the ground that no satisfactory evidence has yet been adduced that an actual make-and-break action is capable of transmitting articulate speech—a feat which the Reis instrument accomplished. That a platinum contact is immensely inferior to a carbon contact, and that no results sufficiently reliable for commercial use have been obtained with the former class of transmitter, needs not to be said.

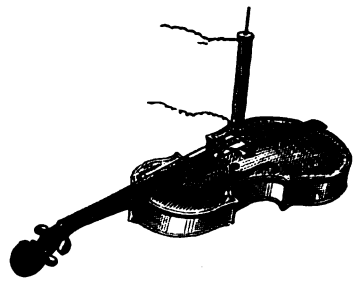

FIG. 2.

So far we have dealt only with the transmitting instrument, but in the Harrison, Cox-Walker trial it was the receiver which was brought upon the scene of action. Reis's original receiver is illustrated in Fig. 2. A careful examination of the figure will probably disclose the fact that in this instrument there were certain superfluous accessories. In fact, it consisted of a violin (lent to Reis by a certain Herr Peter, music-teacher of Friedrichsdorf), upon the bridge of which was stuck upright a knitting-needle surrounded by a coil of silk-covered copper wire. In a paper "On Telephony by the Galvanic Current,"* read before the Physical Society of Frankfort-on-the-Maine, on October 26th, 1861), Reis explains that this wire was magnetised in varying degrees by the successive currents, and when thus rapidly magnetised and demagnetised it emitted tones depending on the frequency and strength of the currents which flowed through it. The violin acted, of course, as a sounding-board to reinforce the sound. This instrument is now preserved in the Garnier Institute at Friedrichsdorf.

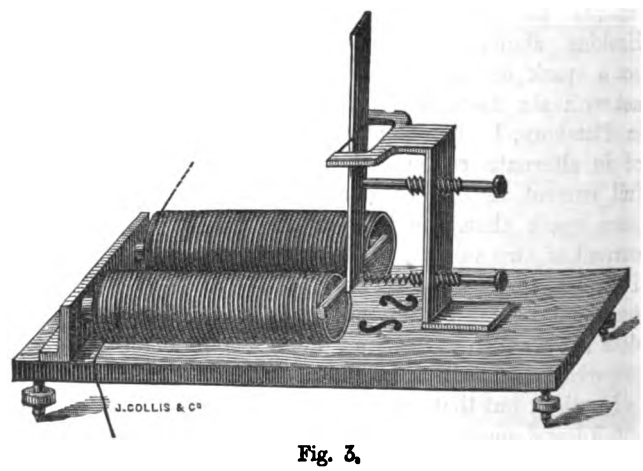

Fig. 3.

The success of the violin experiment naturally led Reis to the construction of a receiver in which the knitting needle was mounted in a horizontal position on a special sounding board. Of this instrument several types were made differing in various points of detail. It is a singular fact that while every one of the Reis transmitters is provided with a more or less elaborate mouthpiece, the receivers were never provided with any similar appendage, although modern practice has proved that this feature is more important in the latter case than in the former.

* See "Philipp Reis, Inventor of the Telephone," by Silvanus P. Thompson, page 15. (E. and F. Spon.) † *Ibid*, p. 21.

* See "Philipp Reis, Inventor of the Telephone," pp. 11—29.

Digitized by Google

The most interesting, and for the purpose of the Harrison, Cox-Walker defence the most important, of the Reis receivers took the shape of Fig. 3. In this instrument we have a double electro-magnet, about 6in. in length, laid horizontally on a wooden sounding board. In front of the poles is an iron rod of elliptical section. In the centre of this armature a wooden lath is attached at right angles; a tension spring and a couple a adjusting screws complete the essential portions of the apparatus.

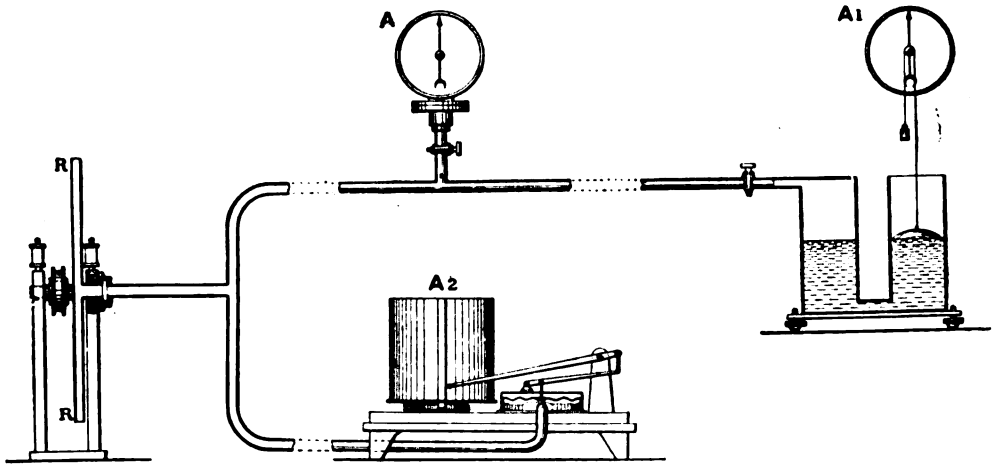
(To be continued.)

THE AMERICAN NATIONAL TELEPHONE EXCHANGE ASSOCIATION.

The ninth annual meeting of this Association was held at Pittsburgh on September 26th and 27th. The papers read were of the usual practical and businesslike character, and a most satisfactory rate of progress was reported in almost every direction which arose for discussion. An interesting paper of a retrospective character on "Ten Years of Progress in Practical Telephony" was read by Mr. Lockwood. The subject is a very tempting one, and in the hands of Mr. Lockwood could not fail to become both entertaining and instructive, and this notwithstanding the fact that the author is not altogether free from the prevailing faults of American technical writers. Had the paper been half as long it would have been at least twice as readable and equally instructive. The progress of the last few years in the art of telephony has in America been as much moral as material. In the words of another member of the association the time has arrived when practical men have completely reversed the old idea that "anything is good enough for a telephone line;" now he would say, "nothing is good enough, at any rate the best is not too good, for it has been most emphatically proved that in the long run the best is the cheapest." This excellent frame of mind has been largely due to the extension of long-distance telephony, and the recognition of the fact that however perfect the intermediate line may be, yet if the local connections are bad the results can never be satisfactory. On this point Mr. Lockwood was very explicit. "It cannot be emphasised too frequently that the short exchange lines have got to be well built; they have got to be built in just the best way we know how; the line wire must be good; the insulators must be good; the joints must be made in the best way." A paper by Mr. E. J. Hall, jun., entitled "Notes on Long-Distance Telephone Work," described the New York-Philadelphia line, which was built to the following specification:—Poles to be not less than 7in. in diameter at the top and from 45ft. upward in length; to be set 6ft. in the ground on straight lines and 7ft. on corners or sharp curves. The poles were prepared for seven ten-pin arms, and three arms were at once put on, carrying 24 copper wires. In addition to the copper wires, one No. 8 iron wire was strung on a top pin to strengthen the line (especially during construction). The utmost pains were taken in guying and bracing, and the good results of this care in building have been fully demonstrated by the nominal expense of maintaining the line since it was finished. The total length of the line is about 100 miles, and on the average 40 poles to the mile were employed. On the completion of the line, notwithstanding the fact that the circuit was a metallic one, it was found that a good deal of "cross-talk" (as the Americans expressively term it) still had to be contended with. "We determined," said Mr. Hall, "not to offer an imperfect service to the public, and months of hard work resulted in perfecting a simple and practical method of absolutely removing all trouble from this cause." Unfortunately the author did not proceed to specify the nature of this sovereign cure. The report of the secretary on Exchange Statistics, and a paper by Mr. W. D. Sargent on "Underground Wires," concluded the business of the meeting. We hope to return to these matters next week. Meanwhile it is gratifying to notice that in America, as well as in England, the "moral," or as we should prefer to call it, the commercial, aspect of telephone engineering is beginning to be fully appreciated.

RUNG'S PNEUMATIC SPEED INDICATOR.

The Thomson-Houston dynamos in the electric lighting shed at the American Exhibition have recently been furnished with a set of pneumatic speed indicators supplied by Messrs. Capito and Hardt. This indicator is the invention of Captain G. Rung, of the Danish Artillery, and has already been in use for about a year and a-half in the Danish Navy, where it seems to have given great satisfaction. The principal merit of this invention lies in its extreme simplicity, and consequent cheapness and non-liability to get out of order. The apparatus consists, first, of a rotating tube acting as a centrifugal exhauster; this is connected with a pipe leading to an indicator, by which the air pressure within the pipe is made to exhibit the number of revolutions per minute of the exhauster. Several different forms of indicator are constructed by Messrs. Capito and Hardt, and in the adjoining illustration three independent methods are shown. In this figure R R is the rotary tube, which is driven from the shaft of the dynamo or other machine. A is an indicator, constructed precisely on the principle of the aneroid barometer, and of which, therefore, no further description is necessary. The scale is calibrated, so as to be read directly in revolutions per minute. Another form is indicated at A_1 in which a U-tube containing water is employed, one branch being connected with the rotating exhauster and the other remaining open to the atmosphere. The difference of pressure in the two limbs, which is proportional to the speed, is indicated, as in the ordinary mercurial barometer, by means of a float attached to a cord passing over a pulley carrying an index hand, and which is counterbalanced by a weight. This is a very sensitive and also a very accurate arrangement. Evaporation is compensated for by means of a small plunger, not shown in the figure, by adjusting the position of which the needle may be set to zero at any time. A_2 represents a recording arrangement, in which the point of a bent lever traces a line upon a sheet of paper wrapped on a cylinder, which is rotated by clockwork. The position of the lever is determined by the degree of exhaustion in an aneroid chamber.



Rung's Pneumatic Speed Indicator.

In addition to the advantages already named, there are two important features which may be said to be almost peculiar to this system. It permits of an accurate indication of the speed of any class of machinery at any distance from the machine itself. And a single indicator may be applied successively to any number of rotators; it is usually sufficient to have only one indicator connected with a common reservoir, to which the pipes from the rotators can enter through stop-cocks. The latter feature is of course an admirable one from the economical standpoint. The arrangement just described, together with the aneroid type of indicator, may be seen at work at the American Exhibition, and those engineers who have not already done so will find it useful to inspect the apparatus before the Exhibition closes at the end of the present month.

NOTICE.

We beg to notify that all correspondence and contributions intended for this Journal should be in future addressed to THE ELECTRICIAN, 1, Salisbury-court, Fleet-street, E.C., instead of to Mr. C. H. W. Biggs, whose connection with it has ceased. Business communications should be addressed to "The Publisher," and cheques and money orders made payable to "The Proprietors."

MANUAL TRAINING.

One of the minor subjects on which an Association of Electrical Engineers, referred to in another column, would claim to have a voice is the manual training of our artisan classes. Various circumstances have combined to bring this vexed question to the front during the present year, and an abortive attempt was made in Parliament to establish a system of technical instruction in our Board Schools under the guidance of South Kensington. We disapproved of this scheme at the time, and are glad that for once in a way Parliamentary obstruction did a useful turn, without meaning it, by compelling Sir W. HART-DYKE to withdraw his Bill. Before next session the subject will, to all appearance, be fully discussed in the public press, and possibly a solution of the whole difficulty may be arrived at by a practical experiment which, if successful, will be worth far more than any Act of Parliament. The Chairman of the London School Board, by far the largest educational machinery in the whole country, has announced that the manual training of boys in the elementary use of tools, the handling of them, and broadly in the exercise of those faculties by which the lads will have to gain a livelihood, has been started in certain of the London schools. The auditor of the Educational Department has, of course, vetoed the expenditure, although it amounted to only a few thousand pounds; but we may safely infer from the Chairman's observations, and from the general approval with which his scheme has been received, that it will not be abandoned for want of funds. It is not pretended that the manual training now being given to boys in these Board Schools—and to which they are certainly as much entitled as are the girls to needlework and cookery—will provide the technical instruction for which there is so great an outcry; but it is a step in that direction, and if followed up will help us to see exactly what it is we need.

What is really needed and what is demanded may be two quite different things, not attainable in the same way, and possibly not both worth attaining. We have before now confessed that we do not quite understand what is meant by technical instruction in relation to the great bulk of the classes who attend elementary schools. A scientific education is out of the question unless the period of tuition be prolonged beyond all reasonable limit; and it is far from certain—we should say the certainty is all the other way—that a scientific education would be of the least use to the Board scholar when he had got it. Yet it is evident that a scientific education is what is meant by those who talk loudest about technical education. The two things are not necessarily the same. Scientific education in the South Kensington interpretation of the term is certainly not technical, and technical education, though in a sense scientific, is by no means what the scientists would prescribe. We very much fear that scientific professors are responsible for much of the delusion prevailing on this point, and we have heard it roundly asserted that the said professors are mainly anxious to enlarge the area of their professorial functions. We want technical education for our workmen, say the manufacturers. We will give it you with pleasure—and for a consideration—reply the scientists; but when we come to look at what they offer it is not at all the thing the manufacturers or their workpeople want. Fairness, however, compels us to add that nobody else has responded to the demand; and it is only natural that scientific teachers should offer the wares they have to sell in the absence of a better commodity. In our opinion the spontaneous experiment now being tried in the London Board Schools, and which will almost certainly be imitated elsewhere, is far more likely to provide the genuine article than anything that has been so far offered in the guise of "technical instruction."

The instruction in certain branches of science has a useful sphere of its own; it encourages learning, spreads scientific knowledge, and, if followed up, results in the rearing of men qualified to superintend and direct by scientific methods the work of the industrial classes. But this is not the technical instruction which is closely related to handicraft, to manual dexterity, to knowledge of a particular calling, and to the complete mastery of its manipulation. If the nation needs the former, by all means let the nation have it; but in that case it must be given to the class that requires it and can use it, not to the workman who needs it not, and who is, we will not say better without it, but better employed in learning what he really needs. On the other hand, if our artisans are deficient in the technical knowledge of their callings, that, too, ought to be given to them. But the technicalities of a trade, unlike the science which embraces all trades, can only be learnt in the workshop; and the best encouragement we can give to that sort of knowledge is to get the pupil into the workshop as soon as possible, and make it his pride and privilege to become an adept. The old system of apprenticeship is perhaps not dead past recall. The powerful trade Guilds might do much to revive it, or substitute something equally useful in its place. Board Schools might

Digitized by Google

do a little by paying the premiums of apprenticeship as a reward of merit. In this way the dignity of labour would be impressed on the youthful mind; and one of the most hopeful signs about this manual training for boys in the London Board Schools is that it will teach them a lesson much needed in these days, namely, that skilled labour is a more excellent thing than book learning. As the *Saturday Review* remarks, there were no good workmen to be found in Laputa, though it abounded in *savants*.

A most remarkable contribution to this discussion comes to us from Germany through our contemporary the *Engineer*. The extract which we printed in our last week's "Notes" under the heading "Technical Instruction," is as startling as it is instructive. We have been sending Royal Commissioners all over the civilised world to ascertain why other nations are so much cleverer than ours. They duly reported that the reasons were to be found in the superiority of the technical training which prevailed abroad, notably in Germany. But apparently this is not the opinion which Germans themselves entertain. If they are superior they do not seem to be aware of it; and what is still more surprising they point to England as a pattern for Germany to imitate. Several German professors have been recently holding forth at various universities on the subject of higher education, the general verdict being that in Germany it is too theoretical, and the scholars too deficient in practical sense. Comparisons are also made between the systems of Germany and England, not to the disparagement of the latter; and a leading industrial paper points out that what is needed for Germany is the scheme of education, technical and practical, which has done such great things for England. We suspect that what is here said of the higher education applies equally to the lower and middle-class. "Schooling" is there pushed to its extremest limits; but manual, technical, and practical education is as much neglected there as here. In Germany, however, they seem to understand precisely what they want; in England we have hardly yet cleared our ideas on this preliminary stage of the problem.

THE PROPOSED ASSOCIATION OF ELECTRICAL ENGINEERS.

Our readers will be glad to learn that the adhesions we continue to receive in support of the proposal for the formation of an Association of Electrical Engineers are so numerous and so cordial that to ensure the success of the scheme little remains to be done except for representative men in due time to come together and set it going. We hope shortly to make a more definite announcement as to this preliminary step. Meantime we shall be glad to hear from correspondents interested in the several branches of electrical industry concerned, either for our information or for publication in this journal. We have indicated already some of the more prominent subjects which a Congress of Associated Electrical Engineers would probably have to take into consideration at the very outset. In due time we propose to discuss these subjects separately, one by one, in our leading columns, with the fullest regard to the business interests of the Association. Our views in a general way have been made known on most of the points in question when circumstances have forced them into public notice; but it is obvious that, taking these matters in hand, so to speak, at a moment's notice, a trade organ is always at a disadvantage unless it is in complete possession of the views of its clients. And before resuming the consideration of such questions as, for example, Electric Locomotion, the Electric Lighting Act, and the attitude of Parochial Authorities towards Telephone Extensions and Electrical Engineering operations generally, we advise the heads of firms to put themselves in communication with us, assuring them that their individual suggestions, as well as their business interests, will receive the carefullest consideration at our hands.

CORRESPONDENCE.

DISTRIBUTION BY TRANSFORMERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: While the subject of the invention of the system of distribution by transformer is under discussion, and there appearing to be a good many claimants for the honours due to those who have really made substantial advances in the art, I may be allowed to give here a few of the leading dates of what appear to me to be the most important advances made:—

1835. Faraday invented the induction coil open and closed magnetic circuit.
1856. Cromwell Fleetwood Varley perfected the closed magnetic circuit transformer, making the iron enclose the conductors and thoroughly laminating the iron, Patent No. 3059.
1857. C. W. Harrison proposed to use induction coils. In a patent granted to him; he proposes to use a primary circuit to supply the coils, and to work lamps from the secondary circuit.
1877. M. P. Jablochkoff patented the use of induction coils in a primary circuit containing the coils in series order, and working lamps from the secondary circuit.
1883. Mr. Rankin Kennedy, of Glasgow, in the *Electrical Review*, of London, pointed out the cause of the failures with coils in series order, and stated that if placed in parallel order they become self-regulating.
1885. Messrs. Zipernowski and Déri patented the use of coils in parallel order.

These dates have been mentioned by Kennedy in his pamphlet, and others, as the leading ones, and, if correct, would seem to support his view that no "master patent" exists on the subject.—Yours, &c., ROBERT MITCHELL.

115, South Woodside-road, Kelvinbridge, October 6, 1887.

PROPOSED ASSOCIATION OF ELECTRIAL ENGINEERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am not sure if I am the Mr. Walker referred to in your note last week, but I may say that I consider the idea a very good one, and shall be prepared to support it, as far as lies in my power. If I understand the matter aright, what you propose to establish is a purely commercial association, to deal with commercial questions. We have similar associations here and at Newcastle in connection with the coal trade. In each of these places a society, or institute of engineers exists, which embraces engineers of all kinds, managers, under-managers, even agents of firms who supply goods to collieries and other works in the district. These institutes have brought before them papers on every subject bearing upon the working of collieries and other works. They go from high science to the most practical details of everyday work; but they do not discuss commercial questions, such as sliding scales, Mines Regulation Acts, &c., except so far as the engineering questions occasionally involved in them go. Side by side with these engineering societies are Coal Owners' Associations, which embrace owners of collieries and the representatives of the large coal-owning companies. These associations do discuss commercial questions, such as those I have mentioned, and others, and they may occasionally discuss new appliances for collieries, so far as their actual working goes.

I take it that the Association of Electrical Engineers you propose to establish would be analogous to the Coal Owners' Association. That they would deal with questions of a purely commercial nature principally, though possibly with others incidentally. Such questions, for instance, as the Electric

Digitized by Google

Lighting Act; an Electric Tramway Act, if one should be necessary; the education of the electrical workman; wire gauges; the providing a standard for electrical engineers to compare their instruments by; the procuring, if practicable, of an Act prohibiting any one from practising as an electrical engineer, or working as an electrical artisan, unless he shall be duly qualified; the procuring of an Act regulating the erection of telephone and telegraph wires over towns; possibly obtaining licences under more favourable conditions from the Postmaster General; and doubtless many others would crop up from time to time.

It should be understood that the questions above enumerated, where they trench upon the engineering department, would only be dealt with by the association so far as the commercial aspect allowed. Thus, the association could lay down the most convenient conditions under which standard instruments should be available; they would not discuss, or at least only incidentally, the structural details of the instruments themselves and their fixings.

I think that the existence of such an association, if properly supported, would be of very great service to electrical engineers generally. It could speak to Parliament, for instance, or to trade councils, with the united voice of the trade. It would almost necessarily acquire importance in the country, as representing a powerful and increasing industry.

There is one thing, however, it appears to me, that it must not attempt to do, and that is to teach. As you have justly remarked, the making of the tool can be left to the societies already existing; its commercial use should be the province of the association.

Perhaps others interested in electrical engineering will give their views on the subject.—Yours, &c,

SYDNEY F. WALKER.

195, Severn-road, Cardiff, October 10th, 1887.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I have already verbally expressed to you the great satisfaction I feel in seeing your excellent suggestion for the formation of an Association of Electrical Engineers taken up so well, and therefore do not propose to dwell on the desirability of such a scheme, which I feel sure will be acknowledged on all hands; yet a very clear idea of the nature and formation of the association is most essential. First of all, in what way will it affect kindred societies, such as the Telegraph-Engineers and the Dynamicables? It is not likely to affect either, for the former is more likely to trouble itself over commercial questions—by the way the Fire Office rules question is completely settled and the Phœnix rules have been universally adopted—and the latter is (or was) essentially a dining society. Can any one tell me whether the Dynamicables exist at all now? One has not heard of them for a long time, although only very shortly before their apparent decease "a local habitation and a name" was announced with quite a fanfare. I remember very well at one of the dinners, when the diners were discussing things more weighty than usual Mr. Joel ventured to suggest that we were only a dining society, and had therefore no right to take up important questions. He was howled down; and yet he was right, we were only a dining society, or why do not we exist to-day? The name, too, "Dynamicable" smacked too much of conviviality, and so for every other reason (if not for its deceased nature) the nature and functions of the new society are not likely to clash with those of the Dynamicables.

The name "Association" is an excellent one, for it suggests its functions at once. We have associations of every kind throughout the country the duties of which are the nursing and fostering the interests of the trades they respectively represent. They are not scientific societies—there are these in addition—they are distinctly trade or commercial societies. For instance, there are the Masters' Association, The Coal Owners' Association, Miners' Association, &c., whose functions, I take it, are similar in their trade to those of the new association in its trade.

Having, therefore, a clear idea of the nature of the association, we are at once enabled to suggest some of the questions which loudly call for discussion and united action by its members. These, however, I think might well be left to a committee, so that the sooner a committee is formed the better. One question I will mention, fearing it may be overlooked, and that is the necessity of an Electric Tramway and Railway Act. The age of heavy electrical engineering can hardly be said to have commenced until we have mastered the "traction" question and taken it up in earnest; it is therefore all important to be prepared with the general outline of a Bill that would meet with the general approval of the electrical world.

Mr. Statter is not new in bringing examples of bad work before your readers, but as yet the association can hardly assume the mantle of the pedagogue, nor can its functions be those of the Board School. Those who do not know how to couple up compound-wound dynamos in parallel had better consult the text books. It would scarcely be decorous to castigate them with the birch of the association.

I wish you, Sir, hearty success in your efforts to carry this suggestion to a practical issue.—Yours, &c.,

J. M. V. MONEY-KENT.

Connaught Mansions, Victoria-street, Oct. 12th, 1887.

EDISON'S SYSTEM OF CONTINUOUS CURRENT TRANSFORMERS.

At Llewellyn Park, one of the pleasantest of the New York suburbs, there is now under construction a central station for the supply of electric light to which a very unusual degree of interest attaches. It represents the first attempt to utilise in practice the principle of the so-called continuous current transformer (perhaps a better name is the "motor-generator"). Messrs. Paris and Scott have hitherto been the sole adherents of that system in this country, but we are not at the present moment aware that they have any plant in actual commercial operation. In the New York scheme the mains are laid out upon the three-wire system, and are to be placed underground. Two dynamos, each giving 600 volts, supply current at constant potential to the motor coils of the transformers, while the dynamo coils each give 100 volts for use upon the consumers' circuits. The generating plant is to be placed in the new laboratory which is now being built for Mr. Edison, and the whole scheme will be carried out in accordance with certain patents taken out by him. Although the existence of these patents was certainly unknown to the world at large, it appears that they date as far back as 1881, 1882, and 1883. It is further claimed for his system that a remarkable economy is effected in comparison with the cost of alternating current transformers for the same output.

Our readers will probably feel that it is desirable to obtain some further enlightenment on the subject before accepting a statement so subversive of accepted ideas.

The following description of Edison's American specifications is taken from our contemporary, the *Electrical Review* of New York:—

1. Electrical distribution system, No. 266,793; dated October 31, 1882; filed December 9, 1881.

2. Apparatus for the electrical transmission of power, No. 265,786; specification filed August 7, 1882; dated October 10, 1882. Consisting of rotating transformers in series and secondary circuits in multiple arc.

3. Apparatus for translating electric currents from high to low tension. No. 278,418; specification filed August 14, 1882; dated May 29, 1883. Induction coil apparatus, the primaries being in multiple arc, with constant potential direct-current mains, the secondary circuit being in multiple arc as usual.

4. System of electric distribution, No. 287,516; specification filed May 14, 1883; dated October 30, 1883. Rotating transformers in multiple arc, with the source of electric current.

In the interesting illustrations presented herewith (Fig. 1) is a diagram representing the disposition of induction coils connected with the rotating alternating device of which Fig. 2 is a drawing.

The induction coils H, J, K, L, M, N, O, P, are built up of a core of laminated iron on which are wound two coils of copper, one of coarse wire as shown by the heavy lines for the secondary circuit, the other of fine wire for the primary circuit. The primary coils are connected, as also are the secondary. From each connecting wire are attached brushes B^1, B^2, &c., for the primary, b^1,

Digitized by Google

b^2, &c., for the secondary circuit. E and F are on the same shaft, and in a portion of their circumferences are inserted metallic contact pieces A, D, C, G. A and G are joined with two continuous rings on which press brushes connected with the dynamo circuit. As the shaft revolves, brushes B^7, b^7, and B^3, b^3 will touch the metal sections, A, D, C, G. The direction of the current will therefore

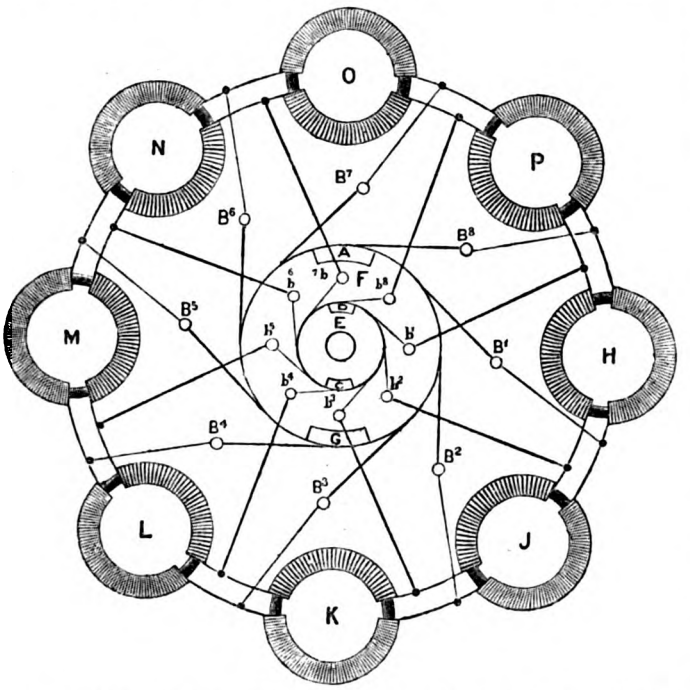

FIG. 1.—Edison's Transformer System of Electrical Distribution. Arrangement of Induction Coils and Commutating Alternator.

be reversed in the primary coils of O and K and induced currents generated in the secondaries of the same coils, which will be taken off by the brushes b^7, b^3, conveyed to two rings and thence

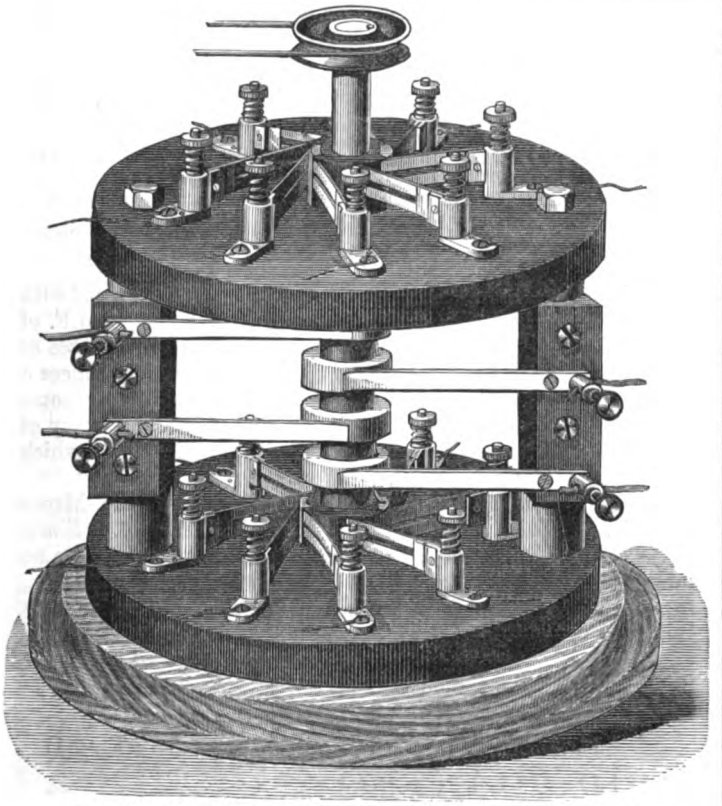

FIG. 2.—Edison's Alternator Used with his Transformer System.

by brushes to the local lamp or motor circuit. As the rotation continues the current in the primaries of the coils is in succession reversed and the induced current in the secondaries commutated. The transformers are connected in multiple arc with the dynamo circuit as shown, by the patent No. 278,418, May 29, 1883, a series system being extremely difficult of regulation. They may be described as a lot of closed magnetic converters arranged in a crown constituting a compound alternating and converting device, the commutation being obtained practically as in the coils of a Gramme ring. According to the ratio of the number of turns on the primaries and secondaries the electromotive force can be raised or lowered. For long distance transmission, using a continuous current of high tension, small conductors only are needed. This current is converted into a continuous current of low tension for incandescent lamp or motor circuits. Reversals of the current are made so rapidly (100-200 per second) that the percentage of conversion is remarkably high. If the primary coils be supplied with current of constant potential the apparatus is self-regulating, and the slight

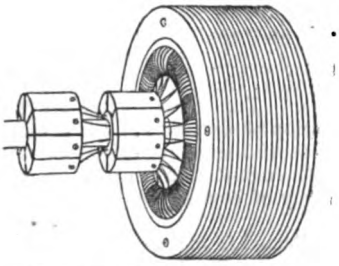

FIG. 3.—Rotation Transformer.

variation of the potential of the secondary circuit is due to the resistance of the wires. Less than the energy of one 16 candle-power lamp is required to operate a motor driving the rotating shaft to commutate current of 200 amperes.

Fig 3 represents a modification of this device. The primary and secondary coils are wound upon one iron core precisely as in a Gramme ring. Outside the whole is a mass of laminated iron, which is stationary, to concentrate the lines of force upon the copper wire. The primary coils of fine wire are connected with the commutator at the end of the shaft, and secondary coils of coarse wire with the remaining commutator.

The coils and shaft revolve. Brushes convey current to the primary coils, the current being reversed in each coil twice each revolution. The reversals of the induced currents in the secondary coils, occurring at the instant, the coil passes from left to right-hand side, as in a Gramme ring. The above device was patented on May 29, 1883, No. 274,418.

Mr. Edison's United States patent 265,786, dated Oct. 10, 1882,

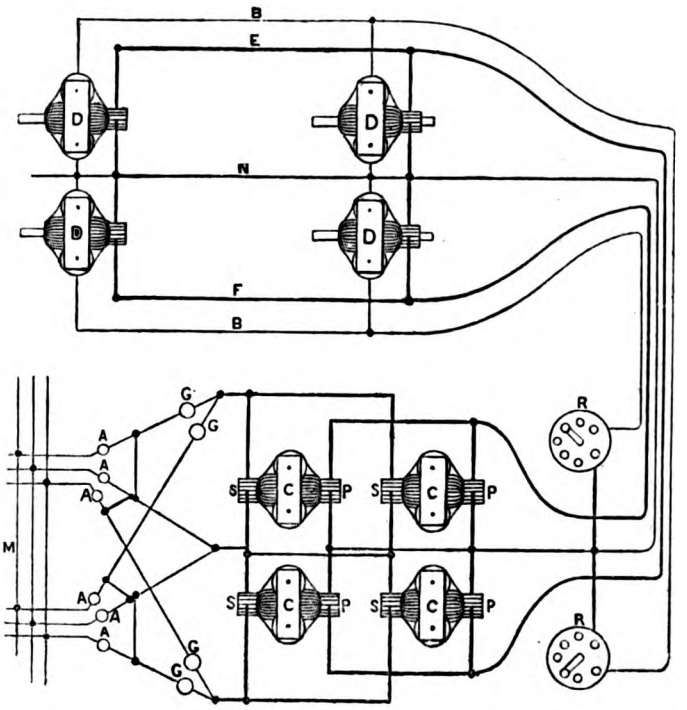

FIG. 4.—Edison's Plan of Rotating Transformers. The Primary Circuit Connected in Multiple Arc with the Dynamos.

describes a system for the distribution of electrical energy in which one set of armature coils of a number of the rotating transformers are connected in series with the dynamo supplying the current. In the secondary circuits of the transformers are placed incandescent lamps or other apparatus. By this system the expense

Digitized by Google

for conductors on long circuits is materially reduced over that of low tension multiple arc distribution. Owing to the difficulties of regulation, Mr. Edison patented October 30th, 1883, No. 287,516, a system of electric distribution consisting of motor generators or transformers, the primary circuits of which were connected in multiple arc with the dynamo circuit, as shown in the diagram Fig. 4.

Dynamos D D D D, connected as usual in the three-wire system, are wound to generate currents of high electromotive force, admitting of the employment of small conductors. The three wires F, E, N, are connected at the sub-station with the primary circuits of the armature of the converters or transformers. The current for the field-magnets of the dynamos passes through the wires B, B, the rheostats R, R, which are at the sub-station, returning over the neutral wire N. The wires B are very small, preferably of iron for economy, and the slight loss of energy in them is of no consequence compared with the convenience of regulating from the sub-station the potential of the current supplied to the converters. The three-wire system is advantageous because the insulation of dynamos and converters will be subjected to one-half the potential of a two-wire system, and because the distribution from the sub-station is easily made on the three-wire system, and economy of conductors and increased area of distribution obtained.

The current is collected from the commutators SS, of the secondary coils of the converters, and is distributed exactly as if the armatures of the converters were driven by an engine instead of a current of electricity from a distant source.

From the indications of the ammeters A and voltmeters attached to pressure wires leading from desirable points on the distributing mains, the attendant at the sub-station regulates the potential of the distributing mains M by the feeder regulators G, and the rheostats R. By the use of the latter it is unnecessary to run back pressure wires from the sub-station to the dynamo station.

The armatures of the transformers or motor generators are wound with two sets of coils, large and small. As their names indicate, they are electric motors, the converting armatures revolving in a powerful field, by the influence of the current passing through their primary circuits. This disposition proves a potent factor in the economy of the system. As there is no belt strain, well-balanced armatures are run at double the speed of a dynamo of the same size. The output is therefore twice that of a dynamo of the same size. At an outlay of 50 per cent. of the cost of the dynamos of the central station, converters can be placed in a sub-station and current distributed four miles instead of less than a mile from the power plant, and at no greater expense for conductors.

The motor generators require much less attention than a dynamo with well balanced armatures; the weight alone of these causes any friction on the bearings. The number of amperes [? ampere turns] of the high and low tension circuits of the armature is approximately the same (any tendency to distort the lines of force and cause a rotation of non-sparking point in a negative direction by the high tension or motor coils is neutralised by the current flowing in opposite direction) of low tension or dynamo coils. There is absolutely no sparking at the brushes of either commutator, and the brushes, when once adjusted, require no change for any variation of load.

ON THE LOCALISATION OF A COMPLETE FRACTURE IN A SUBMARINE CABLE BY BRIDGE MEASUREMENT TO INSTRUMENT ZERO.

BY A. E. KENNELLY.

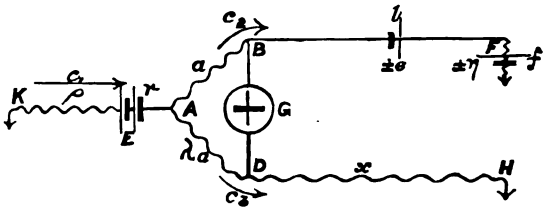
In localising the defect in a broken cable, certain measurements of a resistance $l+f$ have to be made at the testing station, where l is the resistance of the line of conductor between the testing station and fracture, and f is the resistance of the fracture itself. Thus l is the unknown constant quantity required to be determined, and f is a variable quantity which we shall assume to vary inversely as the square root of the current strength traversing it. In common with all circuits of which the earth forms part, l will contain a natural E.M.F. which we may denote by $\pm e$, and the exposed conductor at the fracture will offer an E.M.F. of polarisation we may denote by $\pm\eta$ set up at its surface by the passage of currents, so that $l+f$ has to be measured while containing the total E.M.F. $\pm(e\pm\eta)$.

Two methods are in general use for measuring $l+f$ under these circumstances with a Wheatstone bridge—one, Mance's method, by balancing the cable to true or instrument zero so that no current passes through the galvanometer while the testing current flows; the other by balancing to "false zero" so that the same current shall pass through the galvanometer during the flow of the testing current as after its cessation.

Mance's method employs two measurements of $l+f$ affected with $\pm(e\pm\eta)$ under two different bridge ratios, and yields $l+f$ from these by calculation. It has the advantage of being a "null method," and of being therefore susceptible of greater accuracy in balancing, as the full sensibility of the galvanometer can by means of a short circuit key be utilised. It also needs less manipulative skill. On the other hand, the "false zero" method has the advantage of yielding $l+f$ directly without calculation when such balance has been attained that the insertion or removal of the testing battery produces no alteration in the galvanometer's deflection beyond momentary electrostatic effect.

By causing the testing battery to send different known strengths, not exceeding 25 milliamperes of negative current, through the cable, and observing the change in the corresponding values of $l+f$ to false zero, the value of f can be eliminated and hence l determined with greater or less accuracy. It has therefore been suggested that by observing the strength of current sent to line in the two measurements of Mance's method, the value of f might be similarly eliminated and the quantity l more or less directly calculated. We propose to show that no single pair of Mance measurements can supply the data necessary for the elimination of f, even though the strength of current traversing f be known, and that three such separate measurements are required; but that the lengthy form which the equation evolving l then takes, renders it advisable to alter the current strengths to line, not by changing the bridge ratio coils, but in a determinate manner by the aid of a rheostat in the battery circuit, an arrangement which admits of a simple arithmetical solution to the formula.

We may observe that it is impossible to apply any secondary calculation to the Mance determination of $l+f$ for the purpose of eliminating f, because an inaccuracy exists in the Mance formula, which, without interfering with, but perhaps even enhancing, its practical value for arriving at $l+f$, would nevertheless defeat attempts otherwise indefeasible for subsequently arriving at l.



In the figure the line BF represents a cable of resistance l with a fracture at F, whose resistance is f and whose E.M.F. of polarisation is $\pm\eta$. There is also an E.M.F. in the cable of $\pm e$. AB and AD are the arms of the bridge of resistances a and λa respectively, where λ is generally unity or some power of 10. Connected to A is the zinc pole of a battery of E.M.F. E and resistance r, in circuit with a resistance ρ which is capable of being adjusted.

We shall now briefly follow the evolution of the Mance formula, and in so doing assume that $\lambda=1$ and $\rho=0$. Since, when balance is obtained, no current flows through G, then, no matter what $\pm(e\pm\eta)$ may be, the current c_2 must be equal to c_3, for the points A and B in the circuit ABF have respectively the same potentials as the points A and D in the circuit ADH, and are separated by equal resistances. Let c_2 and c_3 each be denoted by c, then the current in the battery circuit AK mus be $2c$. Then, by Kirchoff's laws—

$$2cr+c(a+x)-E=0 \qquad \therefore c(2r+a+x)=E. \quad (1)$$

$$c(a+l+f)-c(a+x)\mp(e\pm\eta)=0$$

$$\therefore c(l+f-x)=\pm(e\pm\eta) \quad . \quad . \quad . \quad (2)$$

Combining (1) and (2)

$$E(l+f-x)=\pm(e\pm\eta)(a+2r+x). \quad . \quad . \quad (3)$$

By now altering the ratio coils from $\frac{a}{a}$ to $\frac{b}{b}$, and repeating the balance to y instead of to x, we have on the assumption that

Digitized by Google

f, $\pm e$, and $\pm\eta$ are unaltered, a similar equation—

$$E(l+f-y) = \pm(e\pm\eta)(b+2r+y), \quad . \quad . \quad (4)$$

and the current in the cable is now altered from $\frac{E}{a+2r+x}$ to $\frac{E}{b+2r+y}$ by equation (1), or from c to nc where $n=\frac{a+2r+x}{b+2r+y}$, so that we may write equation (4) thus:—

$$nE(l+f-y) = \pm(e\pm\eta)(a+2r+x). \quad . \quad (5)$$

Then, from (3) and (5) $l+f=\frac{ny-x}{n-1}$ . . . . . (6)

$$=y-\frac{d}{n-1} \quad . \quad . \quad . \quad . \quad . \quad (7)$$

where d is the difference $(x-y)$.

If we substitute for n its full value stated above, equations (6) or (7) become $l+f=\frac{x(2r+b)-y(2r+a)}{y+b-a-x}$ . . . (8)

which is the ordinary expression of the Mance formula.

But since the current flowing through f is different in the two measurements, the assumption in equation (4) that f has the same value in both is inaccurate, for the resistance of the fracture being f in the first measurement, will by the law of inverse square roots be $\frac{f}{\sqrt{n}}$ in the second measurement. Suppose a greater than b, then $n>1$ and we shall have $x>y$. Therefore, d is a positive quantity, and the resistance $\frac{f}{\sqrt{n}}$ of the fracture entering into y is less than f entering into x. On this account d will be greater than if f were constant, and equation (7) shows that an excess in the value of d makes $l+f$ in the calculated result too small. That is to say, the calculated value of $l+f$ will be less than the actual sum of cable and fracture in the second measurement, and *à fortiori* still less than the actual sum in the first.

By writing equation (5) more strictly we have

$$nE\left(\frac{f}{\sqrt{n}}+l-y\right) = \pm(e\pm\eta)(a+2r+x). \quad . \quad . \quad (9)$$

whence with (3) $f=\frac{(y-l)(n-1)-d}{\sqrt{n}-1}$ . . . . (10)

and $l+f=\frac{ny-x}{\sqrt{n}-1}-l\sqrt{n}$ . . . . (11)

For example, Sir Henry Mance, in the paper on his method read before the Society of Telegraph-Engineers and Electricians, May 8th, 1884, gives, among others, the following case (*vide Society's Journal*, Vol. XIII., No. 53, page 339):—

$x=421$ $y=392$ $a=950$ $b=95$ $r=200$ $l=351$.

By the Mance equations (6) (7) or (8) with these values

$$l+f=363;$$

but substituting the same values in equation (11), and with $n=\frac{a+2r+x}{b+2r+y}=\frac{1771}{887}$, we have

The more accurate value of $l+f$ in measurement

No. (1) was 379·8ω

" " " " " No. (2) was 371·4ω

Thus, the fracture probably offered 29ω in one case and 20ω in the other, while by the Mance formula it offered 12ω in both.

As already mentioned, the theoretical discrepancy in the Mance formula is no argument against the practical value of the Mance method aiming at $l+f$ only, for since it may be shown that this discrepancy can never practically reach the true value of f, the consequence is simply that less resistance has to be allowed for f in employing Mance's method than in any other except Lumsden's in particular instances.

In the case just worked out we have been able to arrive at f and $l+f$ only because l was given, for had l not been stated there are no means of arriving at these quantities from two measurements only, as we can prove later on. If, however, a third Mance measurement be taken with a bridge ratio $\frac{c}{c}$ and a balance of z, so that the current through the fracture is increased to mc where $m=\frac{a+2r+x}{c+2r+z}$, then we have by symmetry an equation like (9)

$$mE\left(\frac{f}{\sqrt{m}}+l-z\right) = \pm(e\pm\eta)(a+2r+x) \quad . \quad (12)$$

e and η are assumed to remain constant through all three measurements. From (3) (9) and (12) we have

$$l=\frac{(mz-x)(\sqrt{n}-1)-(ny-x)(\sqrt{m}-1)}{(m-1)(\sqrt{n}-1)-(n-1)(\sqrt{m}-1)} \quad . \quad (13)$$

and if $x-z=D$ and $y-z=d$

then $$l=z-\frac{nd(\sqrt{m}-1)-D(\sqrt{m}-\sqrt{n})}{(m-1)(\sqrt{n}-1)-(n-1)(\sqrt{m}-1)} \quad . \quad (14)$$

The last equation supplies the value of l in terms of z and the differences between the balances, together with the ratios n and m, which are found from the equations

$$n=\frac{a+2r+x}{b+2r+y} \text{ and } m=\frac{a+2r+x}{c+2r+z} \quad . \quad . \quad (15)$$

n being greater than unity and m greater than n, or, in other words, the weakest current flowing in the first measurement and the strongest in the third.

Referring again to Sir Henry Mance's paper, we may take the two cases recorded on page 341, where in the first instance

$a=1{,}000$, $b=100$, $c=10$, $x=130$, $y=51$, $z=42$, $r=6$,

whence $n=7{\cdot}006$, $\sqrt{n}=2{\cdot}647$, $m=17{\cdot}844$, $\sqrt{m}=4{\cdot}224$;

in the second instance

$a=1{,}000$, $b=100$, $c=10$ $x=77$, $y=43$, $z=49$, $r=20$,

whence $n=6{\cdot}104$, $\sqrt{n}=2\,471$, $m=12{\cdot}551$, $\sqrt{m}=3{\cdot}543$.

These values inserted in equation (14) yield $l=34\omega$ in both cases. The actual value of l is stated to have been 24ω.

Formula (14) is, however, too lengthy for general use when time cannot be afforded for arithmetical solution, and unless l be small the balance with a ratio of $\frac{10}{10}$ could not generally be observed with much accuracy. Instead, then, of observing to true zero with three different ratios, we will consider the case of keeping one suitable ratio and observing three balances with different resistances in the battery circuit. We shall see that this case is reducible to formula (14), and by treating it generally we shall show that three measurements are required for the determination of l.

Referring to the figure we will assume the bridge ratio fixed at $\frac{a}{\lambda a}$ and the testing current altered by altering ρ.

Let ρ_1 be a certain resistance which will enable a current c to flow to line, and let the resistance of the fracture to this current be f.

Then, because in the circuits A B F and A D H the points A and B have, when balance is obtained, the same potentials as the points A and D respectively, while the resistance separating A and D is λ times that separating A and B, the current c_2 in A B F must be λ times the current c_3 in A D H, so that if the current $c_2=c$ then $c_3=\frac{c}{\lambda}$, and the current c_1 in the battery circuit A K will be $c\left(\frac{\lambda+1}{\lambda}\right)$. Under these circumstances let x be the balance observed. Then let ρ_1 be a certain resistance which will enable a current nc to follow to line, and let the balance observed be y. Then we have

$$\left(\frac{\lambda+1}{\lambda}\right)c(\rho_1+r)+\frac{c}{\lambda}(\lambda a+x)-E=0 \quad . \quad . \quad (16)$$

$$c(a+l+f)-\frac{c}{\lambda}(\lambda a+x)\mp(e\pm\eta)=0 \quad (17)$$

$$n\left(\frac{\lambda+1}{\lambda}\right)c(\rho_2+r)+\frac{nc}{\lambda}(\lambda a+y)-E=0 \quad . \quad . \quad (18)$$

$$nc\left(a+l+\frac{f}{\sqrt{n}}\right)-\frac{nc}{\lambda}(\lambda a+y)\mp(e\pm\eta)=0 \quad (19)$$

Digitized by Google

From these equations, which contain all the data that Kirchoff's laws can supply, it is required to eliminate four quantities, namely, E, $\pm(e \pm \eta)$, c, and f, that is to say the same number of quantities as there are independent equations. Thus, two measurements do not yield sufficient data for the purpose. By taking a third, however, with ρ_2 reduced to ρ_3, thereby increasing the current to line from $n\,c$ to $m\,c$ and observing the balance z, we have

$$m\left(\frac{\lambda+1}{\lambda}\right)c\,(\rho_3+r)+\frac{m\,c}{\lambda}(\lambda\,a+z)-\mathrm{E}=0 \quad . \quad . \quad (20)$$

and $$m\,c\left(a+\lambda+\frac{f}{\sqrt{m}}\right)-\frac{m\,c}{\lambda}(\lambda\,a+z)\mp(e\pm\eta)=0 \quad (21)$$

We have now six equations involving five unknown quantities, and by combining them we obtain

$$l=\frac{1}{\lambda}\left\{\frac{(m\,z-x)\,(\sqrt{n}-1)-(n\,y-x)\,(\sqrt{m}-1)}{(m-1)\,(\sqrt{n}-1)-(n-1)\,(\sqrt{m}-1)}\right\} . \quad (22)$$

This equation coincides with (13) if $\lambda=1$, but when λ is not unity we have

$$l=\frac{\left(\frac{m\,z}{\lambda}-\frac{x}{\lambda}\right)(\sqrt{n}-1)-\left(\frac{n\,y}{\lambda}-\frac{x}{\lambda}\right)(\sqrt{m}-1)}{(m-1)\,(\sqrt{n}-1)-(n-1)\,(\sqrt{m}-1)} \quad . \quad (23)$$

So that if x y and z are divided by λ before being recorded, equation (23) coincides with (13), namely,

$$l=\frac{(m\,z-x)\,(\sqrt{n}-1)-(n\,y-x)\,(\sqrt{m}-1)}{(m-1)\,(\sqrt{n}-1)-(n-1)\,(\sqrt{m}-1)} \quad . \quad . \quad (24)$$

and (14) follows

$$=z-\frac{n\,d\,(\sqrt{m}-1)-\mathrm{D}\,(\sqrt{m}-\sqrt{n})}{(m-1)\,(\sqrt{n}-1)-(n-1)\,(\sqrt{m}-1)} \quad . \quad (25)$$

Thus l is solved in terms of x y and z, also m and n. By causing m and n to assume certain determinate values, equation (14) and (25) takes simpler forms.

Thus if $n=4$ and $m=9$ $\quad l=z-4\,d+\frac{\mathrm{D}}{2}$ . . . . . (26)

If $n=2{\cdot}25$ and $m=16$ $\quad l=z-\frac{9}{5}d+\frac{2\mathrm{D}}{3}$ . . . . . (27)

If $n=4$ and $m=16$ $\quad l=z-2\,d+\frac{\mathrm{D}}{3}$ . . . . . (28)

If $n=2{\cdot}25$ and $m=4$ $\quad l=z-9\,d+2\,\mathrm{D}$ . . . . . (29)

It would of course be possible to enforce these values of n and m by inserting a galvanometer or potentiometer in the line circuit ACF; but this is unnecessary, because we have always

$$n=\frac{(\lambda+1)\,(\rho_1+r)+\lambda\,a+x}{(\lambda+1)\,(\rho_2+r)+\lambda\,a+y} \text{ and}$$

$$m=\frac{(\lambda+1)\,(\rho_1+r)+\lambda\,a+x}{(\lambda+1)\,(\rho_3+r)+\lambda\,a+z} \quad . \quad (30)$$

Consequently to give n and m determinate values, we have (on the assumption that e and η are constant)

$$\rho_2=\frac{\rho_1}{n}-\left(\frac{n-1}{n}\right)\left(r+\frac{a\,\lambda}{\lambda+1}\right)-\frac{1}{\lambda+1}\left(y-\frac{x}{n}\right) . \quad (31)$$

and $$\rho_3=\frac{\rho_1}{m}-\left(\frac{m-1}{m}\right)\left(r+\frac{a\,\lambda}{\lambda+1}\right)-\frac{1}{\lambda+1}\left(z-\frac{x}{m}\right) . \quad (32)$$

In these equations the first two of the three terms on the right hand side are fixed by the first measurement, and x y z must be inserted undivided by λ, not as in equations (25) to (29). If $\lambda=1$, these equations take the following forms:—

With formula (26)
$$\rho_2=\frac{\rho_1}{4}-\frac{3}{4}\left(r+\frac{a}{2}\right)-\left(\frac{y}{2}-\frac{x}{4}\right) . \quad (33)$$

$$\rho_3=\frac{\rho_1}{9}-\frac{8}{9}\left(r+\frac{a}{2}\right)-\left(\frac{z}{2}-\frac{x}{18}\right) . \quad (34)$$

With formula (27)
$$\rho_2=\frac{4\,\rho_1}{9}-\frac{5}{9}\left(r+\frac{a}{2}\right)-\left(\frac{y}{2}-\frac{4x}{18}\right) . \quad (35)$$

$$\rho_3=\frac{\rho_1}{16}-\frac{15}{16}\left(r+\frac{a}{2}\right)-\left(\frac{z}{2}-\frac{x}{32}\right) . \quad (36)$$

and similar forms with formulæ (28) and (29).

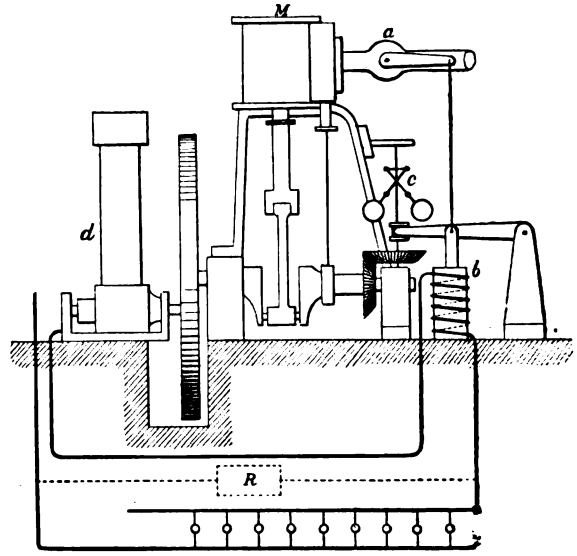
Thus, having satisfactorily observed x with ρ_1, the two first terms of (31) will give a trial value of ρ_2, and generally a single re-adjustment of ρ_2 for the third term will give n with all desirable accuracy when balance is obtained. Similar steps have then to be taken with m and z.

(To be continued.)

MENGES' ELECTRIC GOVERNOR.*

In all installations variations in the output required are unavoidable; sometimes many lamps are on, sometimes few, and various attempts have been made to overcome the irregularities due to these variations by means of electrical governors. Those at present in use, however, only come into action when the change in the quantity to be kept constant (C or E) has already begun to take place. In these the regulator is placed in the circuit in which the current is to be kept constant. If E is to be kept constant, then the current in a shunt of constant resistance must remain the same, and the regulator is placed as a shunt on the main circuit, as at R (while for a constant current system the regulator would be in the main circuit).

In the author's system the converse is the case. To save time, an example of the system for parallel working is given.



The dynamo is supposed to be a simple shunt and regulated by varying the speed; any regulator at present in use would be introduced in shunt at, say, R, and open or close the throttle-valve a according as the current through it is too weak or too strong. It is clear, however, that better regulation would be obtained if, instead of the change affecting the regulation, the cause of change could be made to do so—if, for example, each lamp switch were so connected with the throttle valve that turning the lamp on or off opened or closed the valve a little.

A direct mechanical connection would be impracticable, but an electrical one answers the same purpose. When a lamp is turned on the main current at once increases, and if a solenoid, b, with a soft iron core, be introduced in the main circuit, then the attraction between the two will increase by a definite amount when a lamp is switched on.

If the core be now counterbalanced by a spring, counterweight or other means, so that the core takes up different positions for different current strengths, then cutting a lamp in or out will cause a simultaneous corresponding movement of the core in b. If then the core be connected to the throttle valve, it will have the same effect as if each separate switch were mechanically connected thereto.

By properly arranging the dimensions of the solenoid, core, &c., it may be arranged that the position of the valve shall, according to the number of lamps on, vary speed for the engine and dynamo, so as to maintain constant E.M.F. (The author, in a foot-note, says that very little "hunting" is found to take place.)

The same apparatus may be arranged to keep the speed of a compound dynamo constant, and is even more efficacious for

* Abstracted from the *Electrotechnische Zeitschrift*.

Digitized by Google

this purpose. As in the former case, it requires a certain lapse of time to alter the speed, whereas for constant speed this is obviously not the case.

Since this method is actuated only by changes in the output and not by variations in the driving power, it is generally advisable to use it in conjunction with an ordinary centrifugal governor. The simplest way is to connect the two as in figure. If the position of the core in the solenoid be so chosen that the attraction is only slightly altered by a small displacement, then the weight and attraction of the core act as an additional weight on the governors, the working of which is not appreciably prejudiced thereby.

The author mentions the use of the apparatus at the Elec. Tech. Laboratory of the Hochschule at Berlin, where it was applied to a Siemens compound, worked off an 8 horse power gas engine. It was practically arranged as in the figure, and simply attached to the governor lever by a hook, so that it could be put on or off as desired. Speed was measured on a Buss-Sombart tachometer. With the centrifugal governor alone the variation in speed between full load and running light was about 10 per cent. With the electrical governor in action, there was no difference visible on the tachometer. The apparatus may equally well be used to throw resistance in and out of the field-magnet circuit, instead of acting on the throttle-valve.

In the same way the governor may be used to keep the current constant in a series arc-lamp circuit; in this case it is put in as a shunt across the machine terminals.

With regard to the solenoid and core the author remarks that, under certain circumstances, a somewhat complicated mechanical motion may be necessary. It might be suggested that in such cases an arrangement similar to those in use in the ordinary electrical governors might be employed. On closer inspection, however, this is found not to be so. In his apparatus the moving part (the core) takes up a distinct position for each particular current strength, whilst in other regulators the moving part is at rest only for one strength of current in its actuating coil, and is always in movement until this current is obtained.

The governor does not pretend to completely prevent slow changes, such as are due to warming of the wire on the dynamo, but to counteract sudden changes, which are of necessity constantly occurring, such as are caused by switching lamps on or off, throwing motors in or out of work, stopping or starting electric tram cars, &c.; for all such purposes this arrangement is claimed to be by far the best.

The author then makes some remarks on other means of regulating apart from governors, such as Ayrton and Perry's, Edison's, and compound-winding. The author's aim was to make a regulator which should have the same effect on a dynamo as compound-winding, *i.e.*, regulation preventing irregularities caused by variations in the output, counteracting every irregularity as soon as the first cause was present.

He lays particular stress on the fact that he has obtained complete regulation for changes due to variation of load, not by any complicated arrangements, but by the simple one shown in figure, which, as far as his governor is concerned, is not merely a theoretical diagram but an actual sketch of the whole governor mechanism. Besides the Berlin tests the author mentions that he has tried it experimentally in his laboratory, and has recently obtained perfectly constant E.M.F. in a shunt machine.

With compound winding a perfectly straight line for the curve of E.M.F. is seldom obtained. If, however, the author's regulator be used to vary properly chosen resistances in the field-magnet circuit of a shunt machine, instead of acting on the valve, a perfectly straight E.M.F. curve can be obtained, or even any other form of curve desired.

This method is particularly important for regulating constant current, as for this purpose compound winding is not generally of easy application. As before mentioned, in this case the solenoid B must be in shunt on the main circuit, the series machine being regulated by varying the number of turns on the field-magnet.

This regulator has, under certain circumstances, advantages over compound winding, even when the latter is sufficient so far as regulation goes. In case of a short circuit on the line, compound winding allows the armature to be burnt out. In a simple shunt it is not so. The regulation is in practice just as quick and exact as compound winding, for the core, being so much smaller, changes far quicker in magnetism than the heavy field-magnets. As a final advantage, the author points out that it is a method which can be readily applied to any existing machine.

UNDERGROUND CONDUCTORS FOR ELECTRIC LIGHTING, &c.*

BY PROF. GEORGE FORBES, M.A., F.R.S.

The author has designed the proposed system to fulfil several important conditions:—

1. The conductors and their insulation should be economical in construction.

2. They should be protected from injury by a trough or casing.

3. This trough should be of small cost and its merits must have been well tested.

4. The trough must be capable of carrying conductors at several different potentials.

5. It must be possible gradually to add to the conductors as the consumption of electricity in a district increases.

6. An easy means must be provided for taking branches from the mains into houses.

7. An easy means must be provided for leading the conductors round gas and water pipes and other obstacles.

The first condition can best be secured by having bare copper wire conductors and air insulation.

The second and third conditions by using ordinary cast-iron gas pipes, whose qualities are thoroughly well known, and whose laying and repairing and keeping watertight is every day work in every town in the country.

The fourth condition is attained by having porcelain insulating discs, two in each cast-iron pipe. Each insulator has as many holes through it as there are different potentials to be maintained. These porcelain discs are supported on the iron pipes only at a few points, the intervening spaces allowing drainage in the cast-iron pipes, and also permitting dry air to be forced through a system of pipes.

The fifth and sixth conditions are attained by the special peculiarity of this invention, which consists in using thin split copper tubes with a quarter-inch gap at the split. These are each six inches longer than one of the iron pipes. By pinching the end of one of these tubes and inserting it into the end of another, and continuing the process, a long continuous tube can be made for carrying the bare copper-wire conductors. These continuous tubes pass through the holes in the insulators. The number of copper wires can be added to as the requirements of a district increase. When two-thirds full, these wires are all withdrawn and a bare wire cable filling the whole space of the tubes is drawn through. The wires are drawn through from manhole to manhole. A manhole is placed at each corner of a street; and serves also as a sump for pumping out accumulations of water. When it is required to connect a house to the mains, the iron pipe is drilled and tapped with a one-inch hole. Insulated wires are soldered to the copper tubes of the required potentials, and are led to the houses through inch gas-pipes which are screwed into the hole tapped in the cast-iron pipes. It will be noticed that the split tubes do not act primarily as the conductors of the main current, but mainly as a support for the conductors and secondarily, by contact with these, as a means of connection to the houses, leaving the wires free to be removed or added to.

The seventh condition is to provide for getting round an obstacle. This is best done by having a hand-hole at the ends of the cast iron pipes on each side of the obstacle and joining these by lead-covered insulated cables of the full current-

* Paper read before the British Association Meeting at Manchester, September, 1887.

Digitized by Google

carrying capacity of the system. These cables can be bent round the obstacle, and are in no way a weak point of the system.

The method of laying the conductors in the ordinary routine is as follows:—For a three-wire system for a maximum of 2,000 lamps of ¾-ampere, a 3in. gaspipe may be used. Each insulating disc has three 1in. holes in the positions of the angles of an equilateral triangle. In adding fresh lengths of conductor, three split tubes are first pinched at their ends and pushed into the ends of the three split tubes projecting from the last cast-iron pipe laid. Two insulators are next run along the split tubes to a distance from either end of the tubes of one-fourth of their length. A fresh cast-iron pipe is now run along over the split tubes and their insulators, the latter fitting loosely in the pipes. The joint of the pipes is made with packing in the ordinary way. A new length is added in the same way. Manholes must be placed at each corner of a street, and may be half a mile apart. The cast-iron pipes fit into side holes in these boxes, and are fitted in with watertight cement or packing. Wires are pulled through from manhole to manhole, and may be soldered together across the manhole. Finally, holes are drilled and tapped in the cast-iron pipes beside those houses which require a supply of electricity. Two insulated wires, bared and flattened at their ends, are soldered to those split copper tubes which are of the right potentials. A 1in. gas pipe is screwed into the hole tapped in the main pipe, and the insulated wire is thus led into the house.

DISCUSSION.

Mr. UPTON desired to ask whether the tubes expanded by heat, and what, if any, provision had been made to keep them from buckling?

Mr. PREECE thought it would be of advantage to the section if Mr. Upton, who had had a great deal of experience in America in carrying out electric lighting installations, would give them a little information as to the practice adopted in New York.

Mr. UPTON said that the practice of the Edison Company in New York was the only one with which he was familiar, and it consisted in laying a wrought-iron tube in which in the present three-wire system were placed solid conductors, the tube being then filled with insulating material. The great difficulty that arose in his mind as to the joint in the side of the tube, as exhibited by Prof. Forbes, was that the attachment must be made when the current was passing through. The E.M.F. was present, and unless the workmen could get at and see what they were about they were very much frightened, because when they put 1,000 horse-power across those wires it simply meant a volcano. They had no idea of the amount of power that would come out of the opening.

Prof. FORBES: How do you make your connections?

Mr. UPTON replied that they were all open in a vessel or chamber. The workman saw what he was about An air current was kept running through the whole pipe. In New York city there were some 17 miles of underground tubing made since 1880, and the current was never broken to make the attachments, which were made at the end of the pipes. The give of the joints afforded the necessary expansion. In the Edison system, instead of using, as in this case, porcelain insulators, the wire was wrapped round with long spirals of rope, which held the wires mechanically apart, and everything is put into the tube, attached to a vacuum pump, so that everything was kept dry, and then the insulating material was drawn in, making a very high insulation. He thought that the system exhibited was meant for alternating currents.

Prof. FORBES: Not in the least—for every kind.

Mr. UPTON: The only point that struck me was the difficulty of taking in large wires.

Prof. FORBES: I do not want large wires I sub-divide and use small ones.

General WEBBER thought that apart from other remarks that might be made upon the system proposed by Prof. Forbes, there was one circumstance that appeared to him to be a novel departure to those who were well acquainted with such an arrangement as this system of insulating conductors, and that was the insulation of the conductors by porcelain or other non-conducting materials. Another departure was the use of split tubes, through which the conductor proper was supposed to be drawn. He could not himself quite see the necessity of those split tubes, except as a guide for the copper conductor, which was drawn through them—that was to say, in and out as the case might be—and he did not think himself that the practical result would produce any great convenience. There was one point on which he thought Prof. Forbes would agree with all those who had had any experience in the laying down and maintenance of underground conductors, and that was that wherever there was a joint there must be a box for access to it.

Prof. FORBES explained that the object of the split tubes was only to make a channel, which would be more or less filled. Its chief advantage was that they were thereby enabled to alter the number of wires in the conductor according to their system. The attachments to the houses did not fix them, and they were therefore capable of being drawn in and out.

General WEBBER said that in that case each split tube had a separate wire for a conductor.

Prof. FORBES: And a means of connection with the mains.

General WEBBER: So that there will be a loose contact of the sides which will make a connection between branches?

Prof. FORBES: Yes.

General WEBBER said that one naturally laid great stress upon the desirability of having a box for access to every place where there was a joint, and without in any way offering criticism on the practical result of the system, he thought that if Prof. Forbes would allow in his system a means of drawing in and out the wires, and also that there should be a box for access at every joint of contact, he did not see that it mattered very much what detail of system was adopted.

Mr. SCHOOLBRED remarked that generally the split tubes formed, if even a minimum, a portion of the conductors themselves.

Prof. FORBES: Of course they do to a certain extent, but I simply do not depend upon them.

Prof. SILVANUS THOMPSON wanted to know how the lineman got access to the hole in order to solder the wires on to the tubes inside. There seemed to be a doubtful chance of his making a good joint.

Mr. R. P. SELLON wished to ask Prof. Forbes whether in a large ramified system of so many miles of piping of this kind, with manholes at every other point, it was really possible to keep mud and water out of the system, as otherwise there might be an unpleasant experience of the volcano which Mr. Upton had just spoken of?

Colonel HERSCHELL thought that a little explanation would be advisable as to the connection round obstacles. How was the insulated portion attached, and to what was it attached?

Mr. LAW said that with regard to the observation that had been made as to the difficulty of soldering the wire, he was inclined to think that though there might certainly be a difficulty it might easily be obviated by some simple mechanical arrangement.

Prof. FORBES said he would endeavour to explain the several points raised. Having regard to the time of the section, he was afraid that he had been a little too rapid in his description of the system. Mr. Upton asked what allowance was made for the expansion of the tubes by heat. The very fact that they were simply loosely in contact, that they were made to be and put into contact by pinching one and putting it into the other, left ample room for expansion. There was no difficulty on that account, and the wires which they contained being, as had been explained, thin wires, they were perfectly able to expand without doing any damage, which would be done if, as Mr. Upton had imagined, thick, solid wires were to be passed through them. He might say that the only piping which could not expand was a totally different thing, and that was gas piping. It could not expand, but according to the proportions which had been given the temperature to which the iron piping could be raised was insufficient to produce such an expansion as to weaken the ordinary gas joints. General Webber had asked a question about the split tubes, but he (the speaker) thought the gallant General had misunderstood him. In a great portion of his remarks General Webber seemed to think that the sole object of the split tubes was to be the conductor of the whole current, and therefore very rightly said that the joints were not good enough, and also that there ought to be a box at each joint. He would naturally have boxes for access at points where there were joints of the wires inside the split tubes, and, say, at the corners of streets. Prof. Thompson had asked how the joints were to be soldered. The speaker had worked upon that, and had had a great many experiments before he succeeded in effecting it satisfactorily; but he should have thought that any practical man would have seen the possibility by means of specially designed tools of getting over the difficulty. One thing greatly simplified it. The fact was that he flattened the wire where the joint had to be made, and by the aid of very simple tools there was practically no difficulty in soldering. As to Mr. Sellon's question about keeping out moisture and mud, he could only refer that gentleman to Mr. Aird, who would be better able to answer the question than he (the speaker) could.

Mr. SELLON: Would you not get condensation, which would cause leakage across the porcelain pipes?

Prof. FORBES thought not. All that he could say was that in addition to the advantages that gas people had had they could by this system, while the temperature was at its maximum, force dry air through the tubes to remove all moisture.

Mr. UPTON said that pickholes had been a source of great difficulty experienced in practice in New York.

Prof. FORBES said that he had left that difficulty to be dealt with in the same way as gas pipe breakages were dealt with.

Mr. PREECE, in proposing a vote of thanks to Prof. Forbes for his valuable paper, hoped that the day was not far distant when Prof. Forbes would have an opportunity of making a practical test of the plan he had submitted to the section. He (Mr. Preece) was afraid that it would be found that the difficulties in actual practice would not be quite so easily surmounted as Prof. Forbes seemed to think. There were two questions to be considered. Mr. Sellon had raised one, and that was the condensation of moisture in the pipes. It happened that in the Post Office service they had a large system of air-tight pipes conveying by pneumatic power messages from one part of the city to another. There it was found that in the morning there was a very considerable accumulation of moisture indeed, so much so that special carriers had to be sent through every morning to carry away the quantity of water that had accumulated overnight, and it was often very considerable, and would undoubtedly bring the wires into contact. Another difficulty was with regard to the joints. In all electrical appliances, whether for telegraphic or telephonic purposes, electric lighting, or the transmission of power, the great secret of the successful working of a system was to be sure that they had absolutely perfect mechanical and electrical joints. They must also have their joints in such a position so as easily to get at them and thus secure perfect soldering. They could not do without soldering. It was not of the slightest use to trust to screws or anything of the kind. Another prac-

Digitized by Google

tical difficulty in carrying out any system of the kind was that of meeting obstructions in the streets, such as cellers, sewers, gas pipes, &c. In laying a system of pipes through a town they had dodge a gas pipe here, a water pipe there, and a cellar somewhere else, so that they could not rely upon getting a straight line for their system of tubes. There was nothing so good as discussion on a new subject like this, as it brought out its weak points and enabled its author to set his mind to work to remove any objection that might be raised, which he had no doubt Prof. Forbes would be able to do.

A NEW FORM OF SECONDARY BATTERY.*

BY KILLINGWORTH HEDGES, MEM. INST. CIVIL ENGINEERS.

Secondary batteries or accumulators may be said to have become a necessity in private installations of the electric light, and to be as far advanced as any other part of the lighting system. The batteries which are best known are widely different from those designed by the original inventor, M. Gustave Planté, very little attention having been paid to this type until the matter was taken in hand by a French engineer, M. Phillimond Bailly, whose invention I shall have the honour of describing to you to-day. The battery, which has been termed the Phœnix, is of two kinds Pb-Pb, or lead-lead, and Pb Zn or lead-zinc, and it is to the latter to which I will confine my remarks. The idea of using zinc for the cathode or positive plate of a secondary battery is not new in principle, having been described by several inventors, but its adoption for commercial work was not practicable until about a year ago, when M. Bailly introduced this battery in several installations abroad, where they are still employed. M. Reynier had previously designed a battery with a lead or copper plate coated with zinc, but it failed, and long before this Mr. Swinburne tried a similar plan, employing oxide or carbonate of zinc; but both these arrangements were far more expensive than that of M. Bailly, who prepares his zincs by moulding zinc filings with mercury, and compressing it into a rod or plate.

In a lead-zinc battery the action is as follows:—The zinc plate is attacked by the sulphuric acid in the presence of the peroxide of lead, the latter acting as a perfect depolariser; consequently the reaction is much more energetic than in a lead-lead battery, and the available E.M.F. is, in fact, 2·5 volts, falling to 2·33 when current is taken out. A lead-zinc accumulator is, in fact, a perfect primary battery, in addition to having a large storage capacity, which M. Bailly has found to be five times as much as a lead lead battery with plates of similar surface. In discharging, the zinc plate dissolves in the dilute acid, forming sulphate of zinc, which is decomposed on re-charging, pure metallic zinc being deposited on the zinc plate. The zinc, if properly amalgamated, is thus never consumed, but only dissolved and re-deposited. I have on the table some zinc plates which have been used in a small portable battery which I have used nearly every evening for the past four months, and they are still quite fit for work, although they are simple strips of commercial zinc, and not made on M. Bailly's plan of moulded filings. If the latter is employed I do not see why the zinc plate should not last as long as the peroxide plate. The lead plates of the Planté cell were simple sheets of rolled up lead, and had very little capacity. In the Phœnix battery they are formed of a quantity of fine shreds termed "lead wool" which are interwoven among a number of strips or fringes cut out of a lead plate, so as to form a sort of basket work, which is submitted to pressure, and then placed in the space left between a porous pot and the outside receptacle. The object has been to have a solid metallic conductor permeating the whole mass of the lead wool, so as to pick up the current with a minimum loss due to internal resistance, which has been the cause of failure of those Planté batteries in which lead wool or spongy lead was employed. M. Bailly compares his mode of picking up the current to the "venous system of the human body," in that the main conductor or artery spreads out in every direction much in the same manner as the veins in the body. The capacity of lead plates constructed in this manner is very large, the lead wool giving a surface of 1·5 square metre per kilogramme of lead; every part of the mass is permeated by the fringe-like extensions of the conductor, which being of much larger section than the lead wool filaments remain firm and solid when the latter are completely peroxidised.

Lead-zinc batteries may be constructed in various forms; a convenient arrangement is the circular form which I designed with a view to strength and portability.

The zinc plate is contained in a circular porous pot, conical at the bottom so as to economise the mercury, which forms an excellent electrical connection between the copper conductors and the zinc, without the use of a soldered joint, and admits of the speedy removal of the zinc plate. In larger cells a flat zinc electrode is used, and is contained between two porous plates which are made of compressed sand and offer very little resistance to the current, because they are honeycombed in every direction, and are, in fact, too porous for primary batteries.

The outside case is made of celluloid, a material which is extremely useful for electrical purposes, in that it is unaffected by acid and can be readily moulded into any required shape; also it is much lighter than any other suitable material. For small cells I usually protect the celluloid by a wicker-work covering, but in the larger kind, when they have to be removed for charging, a very light and strong receptacle is made by placing the celluloid in a loose fitting wooden box, and running an insulating material between the two, which effectually takes off any jar that might injure the interior cell. I have found that the most suitable material is a compound known as Phœnix varnish, in that it is almost as cheap as pitch and does not shrink or crack at a low temperature.

A disadvantage attending the use of a lead-zinc battery has been often quoted, namely, that there is a greater fall of electromotive force than with a lead-lead couple. This is not a serious objection, even for lighting purposes, if the discharge is not pushed too rapidly; for driving motors, electrical welding, and other new methods to which secondary batteries may be applied, a fall of electromotive force is of little consequence, and is more than compensated for by the gain of nearly 25 per cent. in the E.M.F. M. Bailly states that he has obtained an output of nearly five times as much from a lead-zinc battery of similar surface to a lead-lead without lowering the E.M.F. below two volts; he has also obtained 28 ampere-hours per kilogramme of peroxidised plate, or 0·08lb. per ampere-hour. In practice I have not obtained so good a result, the average output being 0·13lb. per ampere-hour, which, however, compares very favourably with other batteries.

In the early days of accumulators it was seriously proposed to distribute electricity by their use in the same manner as milk. The all-important factor of the difference in weight of the empty milk cans—as compared with the empty batteries—was apparently forgotten, and the public quickly found this out, although there is a story that a railway company were satisfied with the statement that a set of batteries were empty, and, therefore charged the carriage at the returned empty rate.

It would not, however, be impracticable for a few people living in the same neighbourhood to arrange to take a supply of electricity for lighting their principal rooms, as a small set of batteries on the plan I have here could be easily delivered.

This basket contains six cells or bottles, the total weight being under 1cwt., so that the whole can be carried by one man. The capacity of each cell is 60 ampere hours, and a sufficient number of lamps can be maintained to light a dinner table.

There is a great want at the present time for a small portable battery for railway carriage lighting, to be used as a reservoir for maintaining the lamps when the carriages are uncoupled for the purpose of making up the train. The successful illumination of railway trains by electricity has been practically demonstrated by the North-Western and other companies, who have had trains electrically lighted for some years. The plan which appears to give the best results is to fix a small dynamo and high-speed engine either on the locomotive or back of the tender, giving the driver control of the apparatus, so that he can readily start it from the foot plate. The only objection has been the impossibility of disconnecting the carriages without extinguishing the light. A battery on

the plan I have described would not occupy more space than the receiver which is usually employed with the oil gas system, and would be far safer in every way.

The immunity from accident on our well managed railways is probably the reason that some fearful disaster has not before this attended the use of compressed gas. Railway passengers are ignorant of the dangerous nature of the illuminant, which is generally stored in steel cylinders under the carriages, although these cylinders are amply strong enough to resist the enormous pressure of the gas, but would be easily perforated in the event of a collision, with the result that the liberated gas mixing with air would either explode or in all human probability cause a dangerous fire.

If such an accident occurred in a tunnel—for instance, on the Underground Railway, where the system is generally adopted—there is the additional danger of suffocation from the escaping gas, which would occupy a very large volume of space. An accident took place quite recently on the Berlin Potsdam Railway which ought to act as a warning. An empty goods train ran into a passenger train, piercing the gas cylinder. The liberated gas, being set on fire by the goods engine, flew about in all directions, setting fire to everything in the carriage, in which there were three persons, who, before they could escape, were burnt to cinders. It is stated in the official account that the only remnant of the male passenger was "the buttons on his waistcoat." The gas receiver was a long sheet iron drum placed transversely under a second-class carriage.

It is needless to say that with electric light no such accident could happen, and as the employment of the compressed gas appears to offer the chance of either "cremation or suffocation," it would be far better for the railway companies to improve their existing oil lamp system until they can see their way to universally adopt the electric light.

THE RADIAL DISTRIBUTION OF VARIABLE CURRENTS IN THICK WIRES.

The question of the radial or sectional distribution of variable—and more especially of alternating—currents in conductors of large size is one upon which it will generally be confessed that very little light has dawned as yet upon the average electrician. It is usually, and vaguely, understood that—apart altogether from impedance—there exists a phenomenon by reason of which a given conductor when traversed by an alternating current of given mean square value presents a higher resistance, or causes a greater dissipation of energy, than when traversed by a continuous current of corresponding strength. It is, as a rule, still more vaguely held that this effect is due to a kind of tangential tendency, by reason of which the current density is greater in the exterior than in the interior layers of the conducting wire. The fundamental treatment of the subject is, of course, dealt with by Clerk-Maxwell *(cela va sans dire)*; the question has also been experimentally as well as mathematically investigated by Lord Rayleigh (see *The Electrician*, Vol. XVIII., p. 170, *et seq.*). But hitherto no very tangible conception of the nature of this phenomenon has been placed within the reach of the non-mathematical reader.

We are indebted to a paper read before the Austrian Academy by Prof. Stefan for a simple and intelligible exposition of the kind of action which takes place. Prof. Stefan conveys his explanation by the aid of analogy. Imagine, he says (in effect), a cylinder or cylindrical wire heated throughout to a uniform temperature; let it suddenly be brought into a chamber where the temperature is higher. What will take place? Obviously the outer layers of the cylinder will first rise in temperature and gradually convey heat to the successive interior layers.

Precisely the same order of phenomena occurs if an E.M.F. is suddenly set up between the two ends of the wire or cylinder. The current during the so-called variable state passes first through the outer layers alone, and gradually (using this word in a relative sense) penetrates the inner layers. When the external E.M.F. is suddenly removed, and during the gradual cessation of current due to the self-induction of the conductor, the action resembles, on the contrary, the cooling of a uniformly heated wire on passing into a colder medium—that is to say, the current ceases first, or rather *most quickly*, in the outer layers. Now, imagine that the wire is rapidly transferred to and fro between a hotter and a colder medium. It is quite easy to see not only that waves of heat will pass radially to and fro, but moreover that its condition at any moment depends very largely upon the *rapidity* of the rate of transference. When the rate of motion is sufficiently slow, the waves of heat passing any given point in the radius of the wire follow exactly with the periodic changes of position. The *amplitudes* of these variations have values which decrease from the surface inwards. When the rate of change is increased the amplitudes of the waves get shorter and shorter, and at an infinite velocity the wire would acquire an equable temperature throughout.

The electrical analogue is obvious from what has been already said, the rate of transfer corresponding to the inverse of the periodic time of an alternating current, the heat *conducting* power of the material corresponds to the electric *resistance*. But there is also the inductance of the wire, which plays a part opposed to that of the electric resistance, and which scarcely seems to have any distinct analogy in the heat system.

Prof. Stefan gives some numerical illustrations which are valuable to fix ideas, though many more will be found in the paper of Lord Rayleigh already referred to. With an *iron* wire of 4 mm. diameter, and a periodic time of one 250th sec., the amplitude of the waves of current density is about twenty-five times as great upon the surface as at the axis of the wire. For double the number of vibrations per second the external amplitude becomes only six times as great. The difference of the phases is one-third the duration of the vibration in the first case and one-half in the second. The latter statement implies that the external current is at a given moment actually in the reverse direction to the internal current. For non-magnetic wires the difference is not nearly so marked, and it decreases also as the specific resistance increases. For a copper wire of 4mm. diameter with periodic time of one 500th sec. the difference between the current density at the surface and in the centre is only 14 per cent. If, however, the copper wire be increased to 20mm. diameter then we should get the same difference as in the particular iron wire above quoted.

It is obvious that the result of this non-homogenous distribution of the current is to increase the rate of dissipation of energy, which is of course proportionate in each transverse section to the square of the current in that section. In the case of the iron wire referred to above augmentation of resistance is 48 per cent. at the lower rate of alternation and 100 per cent. at the higher. The resultant effect upon the self-induction is, however, to diminish the value of the coefficient. From this follows the apparent paradox that although the effective resistance is increased by the non-homogenous distribution of current, yet, under the same E.M.F., the current may for the same reason be greater. The effect in decreasing the resultant self-induction coefficient is more marked as the periodic time is lessened, until at length the decrease of impedance from this cause may have a most important influence in increasing the current.

ON THE ELECTROLYSIS OF ALCOHOLIC AND ETHERIEL SOLUTIONS OF METALLIC SALTS.*

BY G. GORE, LL.D., F.R.S.

As very few experiments in the above subject have been published I beg leave to record the following:—The current employed in each case was from six pairs of zinc and platinum plates, excited by dilute sulphuric acid, and the electrodes were, unless otherwise stated, 1·0 × 1·0 centimetre, and about three or four millimetres apart. In each experiment, also, the salt employed was dissolved in 5·0 cubic centimetres of spirits of wine of ·838 specific gravity, and when ethereal solutions were used, the volume of solvent was the same. The electrolysis was continued about 20 or 30 minutes in each case.

Alcoholic Solutions.

Experiment 1.—A solution of ·5 gramme of ferric chloride. With an iron anode, a copper cathode, and a strength of current = ·006 ampere, a very small amount of hard black deposit was formed upon the cathode in half an hour, and it evolved gas when wetted with dilute sulphuric acid. The anode was clean and corroded.

Experiment 2.—With a solution of ·5 gramme of chloride of manganese, a magnesium anode to facilitate conduction, and a copper cathode, the conduction was somewhat free, and the strength of current was = ·015 ampere. Gas alone was set free at the cathode, and a soft coating of magnesia formed upon the anode.

Experiment 3.—The spirit of wine at 6deg. C. was saturated with hydrochlorate of alumina. With a large anode of aluminium, a cathode of copper ·5 × ·5 cm., and a current of ·007 ampere, gas was evolved at the cathode, and colourless saline crystals were found there, but no deposit of metal.

Experiment 4.—A saturated solution of crystalline chloride of cobalt. With a platinum anode 2·0 × 1·0 cm., and a platinum

* From the *Proceedings* of the Birmingham Philosophical Society.

Digitized by Google

cathode 1·0 × 5 cm., and a current of ·007 ampere, the cathode become covered with strongly magnetic crystalline plates of metallic cobalt. The anode was unaffected.

Experiment 5.—A saturated solution of nearly anhydrous chloride of nickel. With a nickel anode, and a platinum cathode 1·0 × 5 cm., and a current of ·01 ampere a trace of metallic nickel, much gas, and a small amount of green solid matter was formed at the cathode.

Experiment 6.—A solution of one gramme of crystals of ordinary stannous chloride. The solution conducted fairly well. With a tin anode, a copper cathode, and a current of ·013 ampere, metallic tin was deposited as a mass of crystals. No gas was set free, and the anode remained clean.

Experiment 7.—A solution of half a gramme of dry solid chloride of chromium, at 6deg. C. With a magnesium wire as an anode to aid conduction, a platinum cathode 1·0 × ·5 cm., and a current of ·01 ampere, at both electrodes gas was evolved freely, and a soft green coating formed; beneath that coating upon the cathode was a film of black solid substance, which evolved gas by contact with dilute hydrochloric acid.

Experiment 8.—A solution of half a gramme of nitrate of uranium. With a platinum anode 2·0 × 1·0 cm, and a platinum cathode 1·0 × ·5 cm., the conduction was moderate, and the strength of current = ·004 ampere. Gas was evolved freely at the cathode, but none at the anode; and a deposit of soft yellow solid substance but no metal formed upon the cathode.

Experiment 9.—A saturated solution of anhydrous chloride of zinc. With a zinc anode 2·0 × 1·0 cm., and a copper cathode 1·0 × 1·0 cm., the resistance was high, and the strength of current = ·007 ampere. No gas was evolved; no coating appeared upon the anode; but a small amount of metallic zinc in the form of a grey powder was deposited upon the cathode.

Experiment 10.—A saturated solution of anhydrous chloride of cadmium. With a cadmium anode 2·0 × 1·0cm., and a copper cathode 1·0 × 1·0 cm., the resistance was large, and the strength of current = ·007 ampere. No gas was evolved; no coating occurred upon the anode; but a deposit of crystals of metallic cadmium formed upon the cathode, and stretched across to the anode.

Experiment 11.—A solution of half a gramme of anhydrous cupric chloride. The strength of current was = ·01 ampere. With copper electrodes, the anode became coated with mixed chlorides of copper, and the cathode acquired a small amount of a dark-coloured deposit of metallic copper.

Experiment 12.—A solution of fused terchloride of antimony. With an anode of that metal, and a cathode of copper 1·0 × ·4 cm., the resistance was large, and the strength of the current = ·004 ampere. No gas was set free. Upon the cathode was first deposited bright antimony, and then loose crystals of that metal.

Experiments 13 and 14.—A solution of arsenic acid would scarcely conduct any current. With a saturated solution of potassic cyanide, and platinum electrodes, the resistance was large; gas was evolved freely from the cathode only, and no deposit was formed upon either electrode.

Ethereal Solutions.

The solvent employed was ordinary methylated ether. The solutions were at 8deg. C., and the other conditions as before.

Experiment 15.—A solution of ferric chloride. With an iron anode, a platinum cathode, and a current of ·008 ampere, no gas was evolved, nor any deposit of metal formed. The anode remained clean, but a soft coating of yellow and black substance formed upon the cathode.

Experiment 16.—With a solution of mercuric chloride and electrodes of platinum the strength of current was = ·003 ampere. No free mercury, but a coating, apparently of mercurous chloride, appeared upon the cathode. The anode remained clean.

Experiment 17.—With a solution of nitrate of uranium and electrodes of platinum, the current was = ·002 ampere, and gas was set free at the cathode only. No metal was deposited, but a thin whitish film formed upon each electrode, and reduced the current to ·001 ampere.

Experiment 18.—With a solution of anhydrous cupric chloride, a copper anode, and platinum cathode, the resistance was very high, and no visible metal was deposited during a quarter of an hour.

Experiments 19 and 20.—A solution of chloride of cobalt was almost an insulator; and one of mercurous chloride, with platinum electrodes, did not conduct at all.

Remarks.—These results, when compared with those usually obtained with aqueous solutions of the same salts, show that alcholic and ethereal solutions are much less suitable than the ordinary ones for the purposes of electro-deposition. The least unsuitable one of the present series was the alcholic solution of chloride of cobalt.

SOUTH KENSINGTON.

EXAMINATIONS OF THE SCIENCE AND ART DEPARTMENT.

(Continued from page 323.)

Second Stage or Advanced Examination.

Instructions.

Read the General Instructions at the head of the Elementary paper.

You are not permitted to attempt more than *eight* questions.

You may only select *two* in Magnetism, *three* in Frictional Electricity, and *three* in Voltaic Electricity.

The value attached to each question is the same.

Magnetism.

21. What effect (if any) is produced (1) on the weight, (2) on the position of the centre of gravity, of a piece of steel by magnetising it? Give reasons for your answer.

Answer. The magnetisation produces no effect either upon the weight or upon the position of the centre of gravity. Both centre of gravity and weight are defined with reference only to the attraction between the earth and the piece of steel, and they are therefore by their definition independent of magnetic forces. Again, the magnetisation does not produce any effect that might be confounded with the effect of an alteration either of the weight or of the position of the centre of gravity, since the magnetic forces on the two poles are equal and opposite, forming a couple. Finally we might, if we pleased, weigh the steel before and after magnetisation, and we should find no difference between the two weighings, provided we took proper precautions to prevent any attraction between the magnetised steel and any part of the balance, as if any such effect took place the result obtained would, of course, not be the true weight of the magnetised steel; and with regard to the dip produced by magnetisation, if that were due to a change in the position of the centre of gravity, it is clear that the amount of dip would be the same in all azimuths, which, as we know, is not the case.

22. Two long magnets are placed vertically with their north poles (A and B) at the same level as the north pole (C) of a compass needle, one being magnetic east and the other magnetic west of C. If the compass is not deflected when the distance AC is twice BC, and if all the magnets are so long that the effects of their south poles may be neglected, show what are the relative strengths of the poles A and B.

Answer.—If A and B be the positions of the north poles of the two magnets, and C that of the north pole of the compass needle, and if M_A and M_B be the strengths of the poles A and B respectively: then, since the force between two magnetic poles is directly pro-

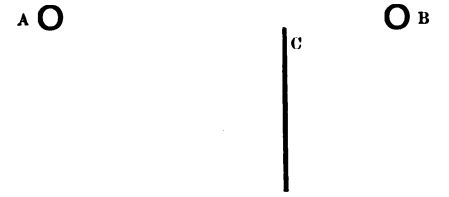

Fig. 19.

portional to the product of their strengths, and inversely proportional to the square of the distance between them, if M_C be the strength of the pole C of the compass needle, we must have, in order that there may be no deflection,

$$\frac{M_A \cdot M_C}{A C^2} = \frac{M_B \cdot M_C}{B C^2},$$

or

$$\frac{M_A}{A C^2} = \frac{M_B}{B C^2},$$

or

$$\frac{M_A}{M_B} = \frac{A C^2}{B C^2} = \frac{4}{1}.$$

So that the strength of the pole A is four times that of the pole B.

23. A compass needle is suspended at the centre of a circle drawn on a horizontal table. A magnet is moved round the compass so that its centre always lies on this circle, and that its length always points magnetic east and west. How and why will the position of the compass needle change as the magnet is carried round it?

Answer.—In the diagrams 20-21 N, E, S, W represent the four cardinal points of the compass, N S is the magnet which is moved round the circle, and *n s* is the compass needle.

For the sake of simplicity we will suppose the compass needle to be small relatively to the radius of the circle, and if the magnet

Digitized by Google

N S be moderately strong, we may practically neglect the earth's directive force.

When the centre of the magnet N S is magnetic north of the centre of the compass needle, as in Fig. 20, the needle will set itself parallel to N S with its poles reversed, as shown. The effect of the earth's force would clearly be to cause its north pole to point slightly to the north of east.

As the magnet moves round towards E, or in the direction of the hands of a watch, its north pole N will always be nearer to the needle than its south pole, and will therefore act more strongly on the needle, which will clearly turn in the same direction, until when the centre of the magnet N S is magnetic east of the centre of the needle, as shown in Fig. 21, the needle will have assumed a direction exactly opposite to its original direction. The effect of the earth's directive force would clearly be to make it assume this position a little before the centre of the magnet N S reached the point E.

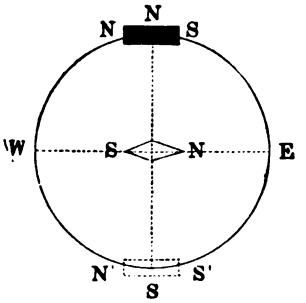

FIG. 20.*

As the magnet moves from E to S, the north pole is still nearer to the compass needle than the south pole, and the compass needle will continue to turn in the same direction until, when the centre of the magnet is magnetic south, as shown by the dotted lines N' S', Fig. 20, the needle will have returned to its original position, having made one complete revolution. The effect of the earth's magnetism will be that the centre of the magnet will have to move a little beyond the point S before the compass needle assumes this position.

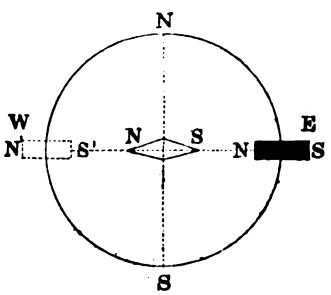

FIG. 21.*

As the magnet continues to move through W to its original position, the south pole will now be nearer to the compass needle, and the needle will continue to move in the same direction as before, pointing east and west, as shown by the dotted lines N' S', Fig. 21, when the centre of the magnet is magnetic west of the centre of the needle ; and when the magnet has returned to its original position, the compass needle will have made two complete revolutions in the directions of the hands of a watch.

24. Two magnets, A and B, are in turn suspended horizontally by a vertical wire so as to hang in the magnetic meridian. To deflect the magnet A through 45 deg. the upper end of the wire has to be turned once round. To deflect B through the same angle it has to be turned round one and a-half times. Compare the moments of the two magnets.

The moments of torsion required to produce the same deflection of 45deg. with each of the two magnets must be proportional to the moments of the magnets. But the moments of torsion are proportional to the angles through which the thread is twisted, viz., 360 – 45 and 540 – 45 respectively.

Thus we have—

$$\frac{\text{Moment of A}}{\text{Moment of B}} = \frac{360-45}{540-45} = \frac{315}{495} = \frac{7}{11}.$$

* In these diagrams the letters indicating the poles of the central magnets should be *s n*, *n s* respectively, instead of S N, N S. The error is due to the engraver.—ED. *E.*

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The accounts of this company, subject to audit, show a profit sufficient to enable the directors to recommend a final dividend of 3s. per share, making, with previous distributions, a total of 6 per cent. for the year ended 30th June, 1887, and also the payment of a bonus of 2s. per share, both free of income-tax, which together will amount to £32,500, being a distribution in the aggregate of 7 per cent. for the past year, leaving a balance of £26,932, of which amount £25,000 has been placed to the reserve fund, increasing that fund to £112,700, and £1,932 carried forward. The above dividend and bonus will be payable on 3rd November. The traffic receipts for the week ended October 7th amounted to £3,966.

CABLE COMMUNICATION.—The Eastern Telegraph Company notifies that the Island of Formosa, in China, is connected by a cable with Foochow. Telegrams for Tamsui, Keelung, and Taipehfoo, in Formosa, are accepted at the rate of 8s. 4d. per word.

ELECTRO-METAL EXTRACTING, REFINING, AND PLATING COMPANY (LIMITED).—It is announced that this company has agreed to sell its works and business to a new company to be registered with a capital of £150,000 in £1 shares, capable of extending the operations in London, as well as by the erection of five other works in the large manufacturing centres. The shareholders of the company have all agreed to accept fully-paid shares in the Extended Electro-Metal Extracting, Refining, and Plating Company (Limited), and in many cases to largely increase their holding. The old company will be liquidated.

GLOBE TELEGRAPH AND TRUST COMPANY.—The directors, at the Board meeting of this company held on the 11th inst., declared the payment of an interim dividend on and after the 21st inst. of three shillings per share on the preference shares, less income-tax, and of sixpence per share on the ordinary shares, income-tax having already been deducted for the quarter ending the 18th October, 1887. The transfer books are to be closed from the 14th to the 21st inst., both days inclusive.

REUTER'S TELEGRAM COMPANY (LIMITED).—The directors of this company have resolved to declare an interim dividend at the rate of 5 per cent. per annum for the half-year ended 30th June last. The same dividend was distributed a year ago.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 7th October, 1887, were £3,249, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

NOTES.

MILE END.—At a recent meeting of the Mile End Board of Guardians notice was given by Dr. Reilly that at the next meeting he would move that the Board take into consideration the desirability of lighting the infirmary by electric light.

SHIP LIGHTING.—The report of the Royal Mail Steam Packet Company states that the directors have decided to fit the following vessels with electric light:—The "Don," "Medway," "Neva," "Nile," and "Tagus." Seven vessels belonging to the company are already supplied.

LIVERPOOL.—We are very glad to learn that the protracted negotiations between the Liverpool Corporation and the Liverpool Electric Supply Company have at length been brought to a favourable termination, and we may shortly hope to hear something of interest from that quarter.

NOTTINGHAM.—Mr. J. Blackburn, of Nottingham, informs us of the acceptance of his tender for the erection of various telephone lines for the Board of Guardians at Stoke-on-Trent; and also for fitting the new Fleming Memorial Hospital at Newcastle-on-Tyne with his improved lightning conductors.

A BREAKDOWN.—We regret to report the fact that, owing to the breakdown of an engine at the Grosvenor Gallery installation, a large number of the lamps supplied by the Sir Coutts Lindsay Company were unlit on the evening of the 18th inst. This was the more unfortunate as it happened on the opening night of Terry's new theatre, which is to be lit from the Grosvenor Gallery.

RINGING CHURCH BELLS BY ELECTRICITY.—Among the gifts to be offered to the Pope on his birthday is a contrivance by a French engineer, named Arragon, for ringing large church bells by electricity. A similar arrangement is, we believe, at present at work in a London church, the apparatus having been designed and erected by some of the students at the Finsbury Technical College.

THE ELECTRO-HARMONIC SOCIETY.—We have pleasure in calling attention to the commencement of the second season of the Electro-Harmonic Society. The first smoking concert of this society will be held at St. James's Hall on Friday, 28th October. The programme for this concert is of an unusually attractive and varied character. We trust that the present season will prove as unqualified a success as the last.

MESSRS. DE LA RUE AND CO. will publish shortly the second volume of "A Treatise on Electricity and Magnetism (Methods of Measurement and Applications)," by E. Mascart, Professor in the Collège de France, and Director of the Central Meteorological Bureau, and J. Joubert, Professor of the Collège Rollin. The work is translated by Dr. E. Atkinson, Professor of Experimental Science in the Staff College.

RYDE, ISLE OF WIGHT.—At the meeting of the Ryde Town Council last week, the Surveyor reported the result of inquiries he had made in a number of large towns where the electric light has been in use, with the view to its adoption in the borough. He moved that the matter be referred back to the Public Works Committee, and no further steps be taken, on account of the extra cost involved. The motion was adopted.

ELECTRIC WELDING IN GERMANY.—A financial association, says the *Elect. Tech. Zeit.*, has taken up the electrical welding patents for Germany of Von Bernardos and Olszewsky, of St. Petersburg. Arrangements are being made in Berlin for erecting the plant necessary to demonstrate its application to industrial purposes. It will be remembered that this method consists in using a carbon pencil to form an arc with the metal to be welded.

IRELAND.—We regret to notice a second outrage on the telegraph wires in a disturbed district of Ireland. In order to prevent information of Mr. O'Brien's midnight meeting last Saturday night—or rather Sunday morning—reaching the reserve forces of police at the neighbouring towns, the wires were cut in several places. More than this, portions of the wires were carried away so that their repair was rendered the more difficult.

A BIG SCHEME.—One of the subjects discussed at the recent meeting of the French Association for the Advancement of Science was the projected canal between Bordeaux and Narbonne. This scheme has been heard of from time to time for twenty years or more. The length of the canal, which will no doubt some day be cut, would be 330 miles, and it is proposed to light it throughout by electricity. Here is an excellent chance for the long-distance systems.

ELECTRIC LIGHTING OF DUBLIN.—On Monday last, at a meeting of the Municipal Council—the Lord Mayor presiding—the debate was resumed on the report of a Committee of the Whole House, with reference to the sufficiency of water-power at Island Bridge for electric lighting, and recommending that the Council should apply to the Board of Works for a license to use electricity for the lighting of the thoroughfares. A protracted discussion took place, and a number of amendments were proposed, but ultimately the report was adopted.

THE ELECTRIC LIGHT IN MONTE VIDEO.—It is reported that a central station is to be erected in this town for supplying the electric light. It is proposed to begin with 1,000 incandescent lamps of 12 candles, these lamps being destined to illuminate warehouses and private houses alike. It is further stated that the contract between the municipality and the gas company having expired, a proposal has been made by the new company to light the streets with incandescent lamps, of which 25 have been installed as a trial. These are said to have fully satisfied the municipality.

MOTOR DYNAMO TRANSFORMERS.—In our "Notes" last week respecting transformers we asked, What are Messrs. Paris and Scott doing? This question would have been unnecessary had we received in due course the account of Prof. Garnett's lecture in the Newcastle Exhibition on Monday, October 10th, which we now publish in another column. From this account it will be seen that Messrs. Paris and Scott have completed a transformer which works either with continuous or alternating currents, and we believe that tests of the efficiency of the machine are this week being made in the Exhibition by the jurors.

POPULAR SCIENCE LECTURES.—The London Society for the Extension of University Teaching are taking a new departure in the introduction of short courses of three lectures; the usual course having hitherto extended to ten weeks. A course of three lectures on "Electricity in the Service of Man" will be delivered by Mr. Lant Carpenter, B.A., at the Essex Hall, Essex-street, Strand, on Wednesdays, October 26th, and November 2nd and 9th. The same course will be repeated at the Shoreditch Town Hall, on Mondays, November 21st and 28th, and December 5th. The fee for admission is one penny per lecture.

THE SUPPOSED NEW FORCE.—With reference to the account we gave last July of Mr. Crookes's investigation of the new force supposed to have been discovered by M. Thore, a correspondent, Mr. W. H. Evans, of Durban, Port Natal, requests us to notify that he obtained similar results as far back as January, 1885, by means of apparatus which he calls the entelechiascope, a photograph of which accompanies Mr. Evans's certified statement of its performances. We should advise our correspondent to put himself in communication with Mr. Crookes; and in any case to describe the instrument intelligibly, so that a rational judgment may be formed of the alleged phenomena.

CROYDON AND DISTRICT ELECTRIC LIGHTING COMPANY (LIMITED).—The prospectus is now being circulated privately of this company, which is formed with a capital of £100,000, in £5 shares, for the purpose of supplying electric light within the borough of Croydon and the outlying districts. The company have entered into a preliminary contract with the Maxim-Weston Electric Company (Limited) for the supply of all the necessary plant. It is also stated that the assurances of financial support are such that the directors consider proceeding to allotment a foregone conclusion, and consequently do not intend to offer any shares of the first issue in the usual manner, by advertisement.

DAS TELEPHON.—Prof. Rouleaux, the well-known authority on mechanism, has addressed a remonstrance to the Imperial Postmaster-General, Dr. von Stephan, against the use of the verb "fernsprechen"—"to far-speak"—for the verb to telephone. Although the Germans consider the telephone a German invention, on the strength of the instrument called "das Telephon," by Philipp Reis, their new-born prejudice against every word of foreign origin has made them christen the telephone as the Fernsprecher, or far-speaker. But Prof. Rouleaux's own suggestion is to substitute the verb "to hift!" We suppose that a telephone will then become also a "hift," or perhaps a "hifter." And the operator a "hiftist."

MANUAL TRAINING.—An "English Merchant," writing to the *St. James's Gazette*, in answer to Mr. Samuel Smith's laudatory account of German education recently published in *The Times*, fully confirms the view maintained in our last week's leader. "English Merchant" says: "It is a great error to imagine that in Germany technical education is extended to common workmen and mechanics." In reality it is confined to "mill owners, overseers and foremen." If Mr. Smith attributes the prosperity of the German working classes to their superior education, he is quite wrong. The German workmen are well employed and earn good wages because a great number of new and important industries have sprung up in all directions during the past fifteen years.

GAS AND ELECTRIC LIGHTING IN PERTH.—The Perth Gas Commissioners, at a meeting held on Monday evening, were called upon to adopt a recommendation by the Gas Committee approving of a report by Mr. Samuel Stewart, gas engineer, Greenock, suggesting an extension of the local gas works at a probable expense of £13,000. A long discussion ensued, and it was eventually agreed to delay taking any action in the matter until the Police Commissioners should have an opportunity of considering the propriety of obtaining a report from an electrical engineer upon the introduction of the electric light into the city. This proposal was carried by thirteen votes, eight members voting in favour of the adoption of the Gas Committee's minutes. We have since learnt that it has been agreed to ask for a joint report from Prof. Ewing and Mr. Duncan Forbes. Mr. Forbes is the engineer to Messrs. Pullar and Sons, of Perth.

THE SUBMARINE TELEGRAPH COMPANY.—The following note appears in the *Bulletin des Sociétés de l'Electricité* of the 13th inst.: "The Cables between France and England.—In our issues of the 19th May and 16th June last we drew attention to the important question of the renewal of the monopoly of the submarine cables between France and England granted to the firm of James Carmichael and Co. This monopoly, conceded in 1851, expires on the 12th January, 1889. For some weeks past active steps have been taken to obtain its prolongation. The question has even been raised in the English Parliament, and the Government has expressed itself very categorically against any kind of postponement. We learn now that the French Government is on the point of granting to the Submarine Telegraph Company the renewal for fifteen years of its monopoly, which has been refused to it in England. We hope that this news is premature, and that the Government will not take a decision so injurious to the interests of telegraphy without obtaining all desirable information, and especially without asking the opinion of the Chambers of Commerce."

RUMOURS.—We hear that there is some prospect of a central station for the distribution of energy being started in a certain quarter of the metropolis.—We hear also that a primary battery will shortly make its public appearance which possesses this highly remarkable property: A single cell has an E.M.F. of, say, E volts, but when two or more cells are joined in series the E.M.F. of *each* cell becomes n E volts, where n has a value lying somewhere between 20 and 30. Consequently, with two cells a total difference of potential of 60 to 80 volts is obtained. We are getting on.—We referred some few weeks ago to a statement in one of our American contemporaries to the effect that an electric motor of American design was about to be placed upon the English market and pushed with American energy and determination. We have now every reason to believe that this rumour is perfectly well founded. The name of the American firm concerned is in our possession, and, while we have every reason to believe that their motor is a good and practicable machine, we are not aware that it possesses any marked superiority to several other motors built on this side of the Atlantic.

THE PRINCE'S-STREET SCHOOL OF ELECTRICAL ENGINEERING.—We learn that at a recent examination conducted by Mr. H. R. Kempe, of the G.P.O., the following students obtained the Vellum Certificate:—(*a*) in Electric Lighting: G. E. Hartmans, with 80 per cent. of the marks; William Green, 78 per cent.; H. R. Braid, 78 per cent.; (*b*) in Telegraphy and Telephony (these students had previously passed in Electric Lighting): G. E. Hartmans, 96 per cent.; W. J. Walters, 96 per cent.; J. R. Cotton, 90 per cent.; H. O. Halford, 90 per cent.; P. J. Pringle, 88 per cent. The course of instruction during the first few months has been lately reorganised by the managers, Messrs. William Lant Carpenter and Léon Drugman, with the view of giving greater prominence than heretofore to the mechanical side of the training. The elements of theoretical and practical mechanics are now systematically taught, as well as the principles of machine drawing. More time is likewise devoted to the short course on Chemistry. Greater facilities are also given to the advanced classes for Lathe and Workshop practice under competent supervision.

THE ELECTRO-DEPOSITION OF IRON.—Prof. W. C. Roberts-Austen, F.R.S., has been making some experiments on the

Digitized by Google

electro-deposition of iron, a process which in Russia is used on a large scale for printing paper money. The bath used is a solution of ferrous sulphate and magnesium sulphate in equivalent proportion, of specific gravity 1·155. The solution must be so far neutralised by the addition of magnesium carbonate that blue litmus paper scarcely shows any acid reaction. A wrought iron anode, about the same size as the object to receive the deposit, must be employed, and the best interval between the poles is found to be four centimetres. Mr. Roberts-Austen finds that the current best suited for an iron medallion had a strength of only 0·089 ampere. The adherence of the iron to the copper on which it was deposited was reduced by coating the latter with a film of metal; but Mr. Roberts-Austen is trying a thin layer of silver iodide on the copper moulds. The deposited metal is very pure, and its magnetic capacity does not appear to be high. The dies for the Jubilee coins were made by this process of electro-deposition. The designs, modelled in plaster, were reproduced in *intaglio* by the electrolytic deposit of copper, and on the copper moulds so prepared iron was deposited. It is of hard and excellent quality, and dies of all sorts for coins have been produced by the reducing machine from such deposits.

THE APPLICATION OF ELECTRICITY TO FARMING.—The following note appeared this week in the *Pall Mall Gazette*:—"Among possible applications of electricity to domestic uses there is one which does not seem to have yet attracted the attention of scientific instrument makers. That is an electric lamp for farmers. At present the husbandman in the country employs either the familiar horn lantern invented by King Alfred and a tallow dip, or the more modern glass lantern, burning benzoline or petroleum. The former gives a wretchedly dim light, while the latter is difficult to light and extinguish, and is, moreover, very unsafe to carry about in linhays filled with straw. An electric lamp would not only give a bright light, but would be absolutely safe. The difficulty is to get a battery of sufficient electromotive force, that shall at the same time be constant and require little or no attention. A dynamo, of course, is out of the question. So, equally, of course, is a storage battery, for it could never be recharged in a country village. If an efficient illuminator could be produced for about seven or eight shillings, it would undoubtedly command an extensive sale." Although we should not be inclined to take so enthusiastic a view as that of the *Pall Mall*, there is no doubt a certain scope for a good portable lamp in this direction, especially when it is desired to carry on thrashing operations after dark. With loose straw about it is, of course, exceedingly risky to thrash with a naked light. Singularly enough this matter has already received attention in southern Russia, where the Stepanoff primary battery is to some extent employed during the thrashing season. The only chance the Russian wheat grower has to dispose of his crop on favourable terms is to get it on the market at the earliest possible moment, before the American and the Indian freights arrive, so that thrashing is often carried on night and day. Some further information on the subject may be found in our issue of Nov. 12, 1886.

LEAMINGTON.—The first public trial of the electric light at Leamington took place on Saturday evening. When the contract is complete, the plant will comprise three horizontal compound engines of 200 horse-power each, by Messrs. Robey and Co., of Lincoln. The double crank shafts of these engines are of steel, and machined out of the solid, having counter-weights attached to each crank-web, to balance the reciprocating parts. The main bearings are three in number, and are cast in one piece with the massive bed plate of each engine (as are the tubular guides also), to diminish the chances of anything working loose. The cross-heads are fitted with cast iron slippers, and the excentric straps are of the same material. Lubrication has been most carefully attended to in all parts of the engine. The power is communicated to the six dynamos through a line of intermediate shafting, which stretches across the whole width of the engine room. Each engine is fitted with a heavy grooved fly-wheel, 10ft. diameter, driving a similarly grooved pulley on the countershaft by means of nine 1¼in. cotton ropes. Six grooved pulleys of 6ft. diameter upon the shafting drive the dynamos in the same manner. The shafting itself is in two lengths connected by friction clutches, and the driving pulleys are also provided with friction clutches. Two of the engines are already in place, and the third is rapidly approaching completion in the workshops of Messrs. Robey and Co. The dynamos are of the Chamberlain and Hookham type, but we shall postpone a description of the electrical arrangements for a separate report. The boilers are 19ft. 3in. in length, 5ft. 1in. in diameter, and have a heating surface of 740 square feet. They are made of Siemens-Martin steel, and have a working pressure of 140lb. The machinery and entire plant are in duplicate. The proprietors of the works are the Midland Electric Light and Power Company, who have arranged with the Corporation to light the Parade and Bath-street, and to supply the light to the Town Hall and the Pump Rooms. A large number of the principal tradespeople have given orders for private supplies of the light.

ELECTRIC STREET LIGHTING IN BERLIN.—The Berlin correspondent of *Industries* reports that at a recent meeting of the Berlin Town Council it was resolved by 91 votes to 3 to light Unter den Linden with 104 arc lamps. Dr. Hagan has been commissioned to report upon the proposed illumination, and is entirely in favour of it. He is of opinion that the installation will be the most perfect example of street lighting anywhere in the world, the amount of light proposed being largely in excess of the usual requirements. Interruption of the light need not be apprehended, he says, as is abundantly proved by the small installation in the Friedrichsstrasse, which has already been at work for three years. After midnight the number of lamps burning will be reduced to 46; and even with this reduced number there will be plenty of light to render the traffic safe. The installation will be erected by the Berlin Electric Works, who have also acquired the central station in the Friedrich-strasse belonging to the Edison Company, and which is very favourably situated, being near the middle of Unter den Linden. In this station there are four Edison 500-light dynamos, each driven by an Armington Sims engine. To this plant will now be added some arc light machines. The present network of cables will be joined to the network belonging to the Berlin Electric Works. The Leipzigerstrasse has already for some years been lighted electrically, there being 36 lamps burning with 11 amperes. The Berlin Electric Works have officially informed the Town Council that they are extending their network within their original district, and that they are ready to go outside their district, provided the Town Council will give them a new concession, in which case they would undertake to erect a new central station in the Spandauerstrasse, to be ready by October, 1889, for the supply of 6,000 lamps of 16 candle power. The capacity of this station would, within three years after the opening, be increased yearly by 6,000 lamps; so as to reach in 1892 a total capacity of 24,000 lamps. The company also offer to build, by October 1st, 1890, another central station in Dorotheenstadt, having a capacity of 6,000 lamps to begin

Digitized by Google

with, and increasing this to 12,000 lamps within two years. These offers have been favourably received by the Town Council.

SCIENTIFIC LECTURES AT THE NEWCASTLE EXHIBITION.—On Monday, October 10th, Prof. Garnett, the chairman of the Lecture Committee and of the Electric Lighting Committee, lectured in the theatre of the Newcastle Exhibition upon some electric appliances. The lecturer showed various experiments illustrating the production of electric currents by different methods, and the storing of electrical energy. A small model brougham, the lamps of which were supplied with electric light from Schanchieff's sulphate of mercury battery, and a number of surgical electric lamps surrounded by water-jackets, and constructed by Messrs. Mawson and Swan, were exhibited. But the chief novelties were the electric welder constructed by Mr. Manville, of the United Electrical Engineering Company, after the plan of Prof. Elihu Thomson, and the transformer of Messrs. Paris and Scott. The electrical welder was furnished with an alternating current from an alternating Gramme machine employed by Messrs. Woodhouse and Rawson in running the Jablochkoff lamps in the engine room, the current passing through 900 yards of No. 12 copper wire. The instrument was manipulated by Mr. Stewart, who has charge of Messrs. Woodhouse and Rawson's installation in the Exhibition. As, in addition to the cables employed in lighting the theatre, there was only one set of leads from the engine room available for experimental purposes, some delay occurred in getting the leads transferred from the alternating machine to the continuous current machine in the engine room in order to exhibit Messrs. Paris and Scott's transformer. During the interval Mr. Stewart suggested trying the alternating current upon the transformer. The armature, of course, remained at rest, but the lamps on the secondary circuit glowed apparently to precisely the same degree of brightness as when a continuous current of the same E.M.F. was employed. In the latter case, of course, the armature rotated, and the electromotive force in the lamps increased until the maximum speed of rotation was reached. The machine appeared to be self-regulating to a highly satisfactory degree, though no exact tests could be made in the course of the lecture; but when half the lamps were switched off the remainder appeared to be practically unaffected. Messrs. Paris and Scott may be congratulated on the behaviour of their transformer on the first occasion of its trial in public.

THE WATER PRIMARY BATTERY COMPANY.—The report of the meeting of the above company, which will be found in another column, contains much information of a most curious character, and will afford plenty of food for contemplation by every intelligent and well-informed mind. The report should be read especially by those who desire to obtain an insight into the latest development of electrical science—and finance. Take, for instance, the remarkable revelation made by M. D'Humy, in reply to Colonel Innes, a gentleman who, premising that he did not profe s to know anything about electricity himself, stated that "a thorough electrician had declared to him that the plates could never last." M. D'Humy, according to the report, said in explanation that "in the water battery there were two kinds of plates—one iron, the other carbon. *The objection referred to the carbon plate.* Undoubtedly if there were any silica in the carbon plate it would perish, but in his invention there was no silica, but pure carbon, and therefore it was indestructible. (Hear, hear.)" In the absence of any "thorough electrician" (beside himself), it was of course easy for M. D'Humy to put his own interpretation upon the objection. But the time has certainly come when M. D'Humy should pay some attention to the difficulties experienced by those who *have* some acquaintance with the subject, and we once more invite M. D'Humy to explain from what source the energy supplied by his battery is obtained. The battery, as our readers are already aware, consists of iron and carbon plates immersed in dilute nitric acid; the carbon takes the form of a deep and narrow box, and the strong acid is poured into this receptacle and filters through into the outer cell which contains the iron. Any ordinary chemist or electrician would conclude that the energy is derived from the oxidation of the iron plate by the dilute acid. But this, as we understand it, is denied by M. D'Humy. We have ourselves seen iron plates which M. D'Humy assured us had been in use for many weeks without perceptible loss. This was twelve months ago or more, and M. D'Humy was not at that time prepared to come before the public, and had not fully made up his mind as to the source from which the cell derived its energy. But if (as he now seems to have convinced himself) neither the iron nor the carbon undergoes any change, we are compelled, in the interests of pure science as much as in those of the investing public, respectfully to demand that we shall no longer be kept in the dark upon this vital point. Does M. D'Humy's battery derive energy from the decomposition of water? or is there some catalytic action between the carbon plate and the nitric acid? or is the E.M.F. entirely due to the endosmose of the acid through the carbon? or is it in some obscure way a thermo-electric effect? a Peltier, or a Thomson effect? is it connected with the Hall phenomenon? has it any relation to Dr. Schüster's recent discovery? or is it an extreme case of metamorphic polarisation of the equivalent atomic charge by incipient molecular disintegration? (Personally, we incline somewhat to the latter view); or, if none of these, then what, in plain words, is M. D'Humy's own explanation of the result which he has obtained? We feel sure that M. D'Humy would not so confidently have promised the investors a return of 100 per cent. within twelve months had he not thoroughly thrashed out the subject to his own satisfaction. And we feel the more emboldened to put these plain questions from the honest and straightforward way in which the chairman of the company announced that "if anyone had the slighest doubt of the validity and value of the machine, and its ability to effect what M. D'Humy said it could, let him put any question to that gentleman, and he would no doubt answer to his own satisfaction and to the satisfaction of them all." We have put our questions and await a reply.

STATE TELEPHONES IN AUSTRIA.—A correspondent in Vienna sends us the following:—The Austrian Government has decided to inaugurate a system of State telephone exchanges, and the official publication of this intention, with detailed conditions of price, &c., was published on the 11th inst. in the official *Gazette*. The document is a curious one, and has connected the State monopoly of telegraphs with telephones, making the telephone seem part of the State telegraph service. The preamble states that the Government have decided to connect mills, factories, business houses, stores, &c., with the telegraph offices whenever requested to do so by them, for the purpose of telephonic transmission of telegrams; further, for the purpose of receiving and sending "phonograms," a new idea, briefly meaning that messages may be dictated per telephone to the post or telegraph office to be sent on from there by letter or post-card per post to any part of the world, or, on the other hand, letters or post-cards received at the post office marked for telephonic transmission

Digitized by Google

can be dictated to the subscriber from the office before being sent on in the usual way. The above, of course, only refers to such towns where no concessions have been granted to private companies, as in those towns where concessions exist the Government does not intend erecting State telephones, as in all of them the exchanges are already connected up with the telegraph offices, and have undertaken the transmission of telegrams to their subscribers, the charges of these existing exchanges being very low already, perhaps the lowest in Europe. The Telephone Company of Austria have now a large number of subscribers in the various towns, and have deserved well of the country by the energetic way in which they have pushed their business in spite of many and varied difficulties. The Government tariff is also guided by the same consideration as the preamble. There is an initiatory installation charge of 50 florins for 500 metres distance from post or telegraph office and 10 florins additional for each 100 metres; then 30 florins annually as a charge for keeping the line and apparatus in order. For telephonic transmission of telegrams a charge of five kreuzers (one penny) for each telegram so sent or received, plus half kreuzer for each word apart from the usual charge for the telegram. For "phonograms" a charge of five kreuzers for each message plus half kreuzer each word, to which, of course, the usual postage is added, and also a small charge for the letter paper and envelope, and, lastly, in the words of the document published, "if a number of such telephone lines are connected up with the telegraph office the subscribers can be connected with each other," and for this a further charge of 20 florins annually is to be made. So the idea of the telegraph is adhered to logically throughout the document, and the real object, viz., the erection of State telephone exchanges in those towns where no private exchanges exist seems really to be only a secondary consideration; it comes in almost as an afterthought. The draughtsman of the document has carried out the ruling idea very cleverly indeed, and if he was also the inventor of the "phonograms" he has not only found a very good word for messages dictated by telephone, but if this idea succeeds, he has initiated quite a new convenience for the public, especially as the private exchanges are sure to adopt these with the permission of the Government. It will be seen that the charge is really 50 florins per annum plus a special installation charge of 50 florins plus 10 florins for every 100 metres beyond the original 500. The charges of the Telephone Company vary according to the size of the towns, the larger being, of course, dearer, but they vary from 60 florins to outside 90 florins a year, out of which 10 florins a year have to be paid to the State, a very large royalty indeed, and one which gives the State an excellent revenue. So the charges do not vary much from those proposed for the State Exchanges.

INDUCTION TELEGRAPHY TO AND FROM BODIES IN MOTION. At a recent meeting of the New York Electrical Club Mr. Charles A. Cheever read a paper upon the above subject, which is now attracting considerable attention in America, and which, as our readers are aware, has received practical application upon several important railroads. In tracing the history of the invention Mr. Cheever referred to the paper read by Mr. Willoughby Smith before the Society of Telegraph-Engineers on Nov. 8th, 1883, in which the following passage occurs:—"Now it has occurred to me that volta induction might be employed with advantage in various ways for signalling purposes. For example, one or more wire spirals could be fixed between the rails at any convenient distance from the signaling station, as that, when necessary, intermittent currents could be sent through the spirals; and another spiral could be fixed beneath the engine or guard's van and connected to one or more telephones placed near those in charge of the train. Then, as the train passed over the fixed spiral, the sound given out by the transmitter would be loudly reproduced by the telephone, and indicate by its character the signal intended." At the time when this paper was being written Mr. Phelps, whose system is now a practical success, had just commenced to experiment upon the identical lines independently laid down by Mr. Willoughby Smith. It appears, however, that the earliest record of the idea is contained in a United States patent, issued in 1881, to another W. Smith (Mr. Wiley Smith). In this specification the plan of using a "buzzer" does not occur, and the patentee relied upon the direct inductive effect of Morse key makes-and-breaks between an adjacent wire and a closed circuit (including a telephone receiver) carried by the train. It is obvious that the method of Phelps is capable of giving far better results in practice, but yet Mr. Cheevers has found that with a receiver having 700 to 1,000 ohms resistance it is possible to read a message when the terminals of the instrument are merely attached to the opposite ends of the roof of a single car. The distance of the inducing circuit and the battery power used is not given. For the Phelps system as at present in use a battery of twelve chromic acid cells is employed. Each cell is 2 inches wide and 4 inches deep. This battery is closed on an induction coil having a primary coil of about 3 ohms and a secondary coil of about 500 ohms, and provided with an ordinary vibrating make-and-break. Messages are sent with a Morse key placed in the secondary circuit. The receiving telephone has a resistance of about 1,000 ohms. The line wire is stretched on poles 16ft. high at an average distance of 8ft. from the rails. The train circuit is made up of wires carried through the train from car to car and fixed just under the roof. In concluding the paper Mr. Cheever said: "I have not taken your time with the discussion as to the various uses and advantages which may be obtained by the induction telegraphy, nor as to the numerous improvements which I know to be under experiment and outline for the future. Arrangements are already perfected whereby duplexing, or even quadruplexing, may be accomplished. Experiment has been made for transmitting articulate speech to and from moving trains, and whether this can be reduced to a practical success remains to be seen. As far as we have gone, we have met with encouraging results with the line wire situated 8ft. distant from the moving car. There seems to be no reason why, with the proper adaptation of the elements employed, communication between ships could not be arrived at. Telegraph line wires may in the future be laid through our rivers and sounds, and with suitable coils upon the boats moving up and down the streams communication may be had with them. Edison, Gilliland and Phelps have all experimented in the direction of ship telegraphy, and the results give great encouragement of ultimate practical success. To conclude while the results are now all that can be desired for telegraphic communication to and from railroad trains, there is still a vast field of other uses for induction telegraphy yet open for experiments to make them practical and useful." In the discussion which followed, Lieut. Toppan called attention to a singular phenomenon in connection with the working of static induction, stating that in crossing the iron bridge which spans the Mississippi river between Minneapolis and St. Paul, and which is several hundred feet long, with the wires a number of feet below the bridge, there was no apparent falling off in the inductive effect, and the operators were able to work as well at that point as anywhere else on that branch of the Chicago, Milwaukee and St. Paul Railway.

THE PRACTICE OF DYNAMO DESIGN.

BY GUY C. FRICKER.

(Continued from page 435.)

Thus far, dynamos of the most usual types have been considered, and their design reduced to as exact a process as the present knowledge of the subject admits. The chief uncertainty has clearly been that relating to the magnetic leakage from pole to pole, or rather from all points on the magnetic circuit differing from each other in magnetic potential. We have not been able to gauge this quantity with any great degree of accuracy, and have been perforce content to make a fairly near approximation to it in the application of a very simple rule.

It is also clear that this magnetic leakage is the great defect in modern dynamos, making it necessary to provide field-magnets of enormous cross section compared with the actual number of lines which pass from them through the armature. This objection has been partially met by the so-called iron-clad dynamo, in which the magnetising coils are surrounded by the iron in which the induction is required.

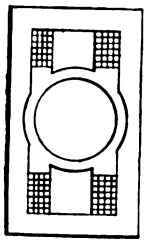

FIG. 17.

A good illustration of this arrangement was given by Kapp in a series of articles on dynamo design and construction in *The Electrician*, Vol. XIV., page 391, and for the benefit of those who may be unable to refer to this number the figure is here reproduced. Viewing the exciting coil in section it is evident that by enclosing the copper by iron in the way shown, the magnetic "whirl" or sheath is conducted without permitting any lines to stray into the surrounding space. There are this design, however, certain lines which pass across the air spaces from pole to pole without entering the armature, and are thus useless for the production of E.M.F. in the circuit.

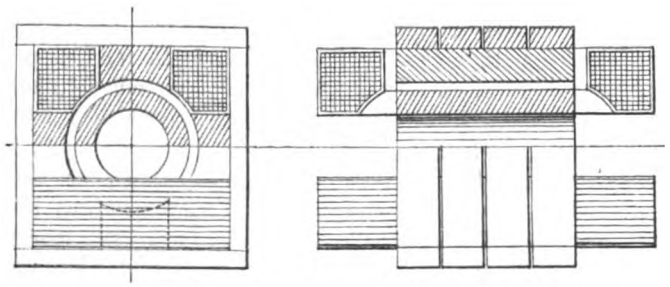

FIG. 18.

In a modified form of this machine designed by the present author this waste field is minimised and the geometry of the circuit so arranged as to secure a very large activity for the cubic space occupied. On a reference to the illustration of this machine in Fig. 18 it will be seen that the section of the exciting coil is almost entirely surrounded by the iron in which the induction is required, the only gaps being those necessary for the introduction of the armature winding. In spite of the apparent merits of the above arrangement the results in regard both to weight and efficiency are by no means encouraging. To give point to this we will calculate the dimensions of a 10-unit machine of this type, and compare it with those previously dealt with.

Starting with the following values for the fixed quantities viz. :—

$p = \frac{1}{3}$	$M = 20$
$q = 3$	$P = 4$
$\beta = \cdot05$	$\gamma = \cdot7$
$\rho = \cdot9$	$\mu = \cdot6$

we get $R = 3\cdot6 \times 1\cdot154 = 4\cdot16$; say, $4\frac{1}{8}$in.

$N = 243$

$A = \cdot00494$

$\mu\beta R = \cdot126$

whence, making two layers, the section of wire is $\cdot0786 \times 063$ giving $\mu = \cdot61$.

By adjusting N to 240 turns we should get a 60-part commutator with 4 turns to each section. The total number of lines passing through the armature is

$$Z = \frac{117 \times 10^6}{240 \times 1000} = 488.$$

Without any elaboration on the point we may assume that, including the waste lines, which in this design are very few, the total induction will not be greater than 550—that is, 225 lines through the section $pq\gamma R^2$. The section of the field-magnets will thus be $AB = \frac{225}{18 \times \cdot8} = 15\cdot6$ square inches.

The cores may be conveniently arranged in four pieces, each 3in. wide, placed side by side, with a short air gap between contiguous bars; the thickness of these bars would be $\frac{15\cdot6}{12} = 1\cdot3$in., or say $1\frac{3}{8}$in. The magnetic resistances may be taken as follows :—

$$R_A = \frac{4}{11\cdot9} = \cdot335$$

$$K R_A = 2\cdot45 \times \cdot335 = \cdot825,$$

and from the former rules $\delta = \cdot3$in. In this design the angular extent of the pole-pieces may be increased to $\frac{\pi}{3}$, because they cover the outer portion of the ring only. We then get

$$R_a = \frac{1440 \times \cdot6}{53\cdot7} = 16\cdot1;$$

also in this case

$$R_F = \frac{L}{AB} = \frac{19\cdot5}{16\cdot5} = 1\cdot18 \; ; \; K_2 R_F = 2\cdot45 \times 1\cdot18 = 2\cdot9.$$

Thus $p_1 = 16\cdot925 \times 488 = 8300$; $p_2 = 2\cdot9 \times 550 = 1600$,

and $P = 9900$.

This exciting power must be exerted by each of the bobbins, the parallel magnetic circuit excited by one bobbin only having been considered above.

The procedure for determining the size of these exciting coils must be different to that previously adopted, because we no longer have the same conditions of ventilation. In the former designs the current density in the field coils has been about 1,300 amperes per square inch for this size of machine; it will, therefore, be probably quite safe to assume a density of 1,000 amperes for the coils in question. The variation in density with the linear dimensions will follow the same law as before. Retaining the former average current of 7 amperes, the section of wire is ·007 square inch, which corresponds to a circular wire of ·0942in. diameter, and gives

$$\mu_1 = \cdot885 \times \frac{\cdot0942}{\cdot0942 + \cdot02} = \cdot73$$

The total number of turns are $\frac{9900}{7} = 1414$, and the area occupied by the section of these wires is

$$\frac{1414 \times \cdot007}{\mu_1^2} = 18\cdot6 \text{ square inches.}$$

The sectional area provided by the proportions shown in the figure is about $23\frac{1}{2}$ square inches, which includes the necessary margin for the magnet case.

On analysis we find the weights of the various parts to be as follows :—

Armature core	60lbs.
Magnet bars	280 ,,
Pole pieces	190 ,,
Armature winding	11 ,,
Field-magnet winding	315 ,,

The total weights are thus :—

Iron	530lbs.
Copper	326 ,,

The resistance of the armature will be ·0533 ohm and the loss in watts 533. The loss in the magnets is 610 watts, the electrical efficiency is thus only $89\frac{1}{2}$ per cent.

Before concluding the subject of continuous current dynamos, an interesting point on the magnetic resistance of the air gap δ may well be mentioned. For a considerable time

Digitized by Google

Mr. Kapp had been puzzled by the disparity of his experimental figure of specific air resistance, 1,440, and the true figure of 1,860, more especially because experience has shown that 1,440 is quite high enough to fulfil the conditions of the actual case. At the British Association Meeting at Manchester he had some conversation on this matter with Prof. Ewing, who pointed out that although as compared with *iron* the resistances of air and other non-magnetic substances are identical, yet, compared among themselves, discrepancies of even 100 per cent. might exist; in fact he, Prof. Ewing, had found copper to be much more permeable to magnetism than air, and since a great part of the gap δ is composed of copper a solution of the mystery may thus be found.

There are many other forms of the continuous current dynamo, to nearly all of which a treatment closely analogous to that given in the foregoing papers may be applied. No good purpose would be served, however, by multiplying examples; this part of the subject of dynamo design will therefore be closed with the typical forms which have here been considered.

(To be continued.)

THE NORTH METROPOLITAN TRAMWAYS COMPANY AND THE ELIESON ELECTRIC LOCOMOTIVE.

The extended series of trials of the Elieson and other systems of electric traction which are taking place upon the lines of the North Metropolitan Tramway Company cannot fail to have a marked influence upon the progress of electric traction in this country, and our readers will doubtless be glad to have an authentic account of the results so far obtained, and especially of the impression which has been made upon the Directors of the Tramway Company.

On the 6th of June the Elieson locomotive commenced running upon the line between Stratford and Manor Park, a distance of four miles and a-half, and since the early part of August, when certain initial difficulties were finally overcome, the service has been conducted with perfect regularity. The very fact that we have all along regarded these experiments with an earnest desire for their success has led us to refrain from chronicling in our columns the petty difficulties and mishaps which are necessarily incident to the early days of such an undertaking. The failure of the connection of a battery cell may stop a car, and may suggest the desirability of altering the pattern of the binding screw, but it is not a criterion of the value of the system, and such breaks-down should, in our opinion, no more be made the subject of public comment in a technical journal than if a similar mishap occurred in a laboratory experiment. The propriety of such reticence is the more obvious when, as in the present case, the experiments are conducted at private charges and not with the money of a public company. Mishaps were not infrequent when the Elieson Electric Locomotive Company first undertook the Manor Park service; on one occasion the whole of the engines were withdrawn for several weeks. This misfortune arose from the continued snapping of the armature wires at the point where they are connected to the commutator. The Elieson system does not, however, rely upon any special type of motor, and the machines now furnished by Messrs. Paterson and Cooper do their duty extremely well. During the last ten weeks the service has been conducted with just the same degree of regularity as that of the horse cars. Our authority for this statement is not derived from any mere off-hand estimate, but from a personal inspection of the daily records, which have been most carefully compiled by the officers of the Tramway Company, and which have very kindly been placed at our service by Mr. Adamson, the general manager of the North Metropolitan Tramway Company. In these records entries of a minute description are made relating to the daily performance of each engine and car. Some two months ago we went over the line in company with Mr. Elieson; the plant had at that time just been brought into good working trim, and the impression which we received after a careful inspection of the whole of the arragements was one very favourable to the system as a practicable mode of traction. This impression is fully borne out by the experience since gained and by the testimony of the Tramways Company. "There is no doubt in our minds," said Mr. Adamson, "that the Elieson engines are fully capable of doing the work which we require." So far so good. But this does not touch what is, after all, the question of supreme importance, and the only question with which the Tramway Company professes to be concerned. It is obvious that no amount of technical excellence in the design of the gearing or in the arrangements for charging the cells, no degree of smoothness and regularity in the working, will permit us to overlook the all-important question of finance, and until the working cost, rate of depreciation, and capital charges have been fully worked out, the commercial value of the system remains an unknown quantity.

Unfortunately it is yet too early to arrive at definite conclusions on these points. This is admitted on both sides. The question of depreciation in particular is one upon which a much more extended experience is required. As to working cost we have this much to go on:—The first offer made by the Elieson Company was based upon a rate of 3½d. per car mile. The actual working expenses for horse traction upon the North Metropolitan Lines are a trifle over 5d. per car mile. The Tramway Company voluntarily offered to make the rate 4½d. instead of 3½d., stating that their object was not to effect an immediate saving, but to obtain a thorough test of the practicability of the system. The Elieson Company inform us that they have not been able as yet to determine the exact cost per car mile which has been incurred, but, as will presently be seen, they are quite willing to accept a more extensive contract at the same price.

Now as to capital account. On the North Metropolitan lines every car is worked by 10 horses, with one spare animal. The average price paid is about £36 to £37. The life of a tram horse is known to be a short if not a merry one, and the rate of depreciation is high; in fact, at the present time horse-flesh and secondary cells probably run a close race in the matter of depreciation, with the odds somewhat against the horse. There is, moreover, reason to believe that the breed of horses is not improving so rapidly as that of lead plates.

Under the system of separate locomotives, with cells permanently fixed in position, it is necessary to have two engines for every car. The cost of these engines is about £542, made up as follows:—Car, £95; 80 accumulators, £240; motors and gearing, £207. This represents an initial expenditure of about £1,100 per car, as against only about £400 for horses, so that to put the two systems on an equal footing in this respect the depreciation must be at only one-third the rate in the former case.

On another matter relating to capital charges it is unfortunate that at present something in the nature of a deadlock exists between the two companies. The facts are these:—The Elieson Company has hitherto been permitted to use part of the premises of the Tramway Company at Stratford as a charging station and engine house. These premises are already fully occupied by the seven engines at present at work. Now the Tramway Company are willing that the Elieson Company should undertake the whole of the traffic on the Manor Park line; but this would require about twenty cars. The Elieson Company have therefore proposed at their own expense to equip a new station at the Manor Park end of the line, and to build new self-contained cars for the additional service. They ask, however, that the Tramway Company should purchase or rent the land and erect the necessary sheds. This the Tramway Company are not inclined to do. They are perfectly willing to contract with the Elieson Company for the performance of the service, but do not see their way to incur any initial outlay. And so the matter stands.

Meanwhile we may add that preparations are now being made for working the Barking line solely by electric traction, the arrangements having been placed in the hands of the Electric Traction Syndicate, who will employ motors of the Immisch type. We are informed that in this case the initial outlay does not exceed that for horse traction. Self-contained cars will be employed, which are being constructed by the North Metropolitan Tramway Company.

NOTICE.

We beg to notify that all correspondence and contributions intended for this Journal should be in future addressed to THE ELECTRICIAN, 1, Salisbury-court, Fleet-street, E.C., instead of to Mr. C. H. W. Biggs, whose connection with it has ceased. We deem it right to add that no other change whatever has occurred or is contemplated in the proprietorship or management of this Journal.

ANSWER TO CORRESPONDENT.

MR. C. G. MALLESON, MELBOURNE.—*Dr. Cornelius Herz is the editor of "La Lumière Electrique," and no doubt you would be able to obtain from the office of that journal the information which you seek.*

MORE ABOUT THE PROPOSED ASSOCIATION.

It was not our intention to recur again so soon to the subject of the proposed ASSOCIATION OF ELECTRICAL ENGINEERS, especially as the scheme is rapidly gaining favour throughout the profession, and is experiencing no serious opposition from any quarter whatever. But some of the letters which reach us, and some of the comments which have appeared in the technical and trade journals supporting our proposition, betray a certain divergence of opinion as to what the objects of such an Association ought to be; or rather a misapprehension of the particular objects we ourselves had in view when recommending its formation. Indeed, in the few places where we observe a languid interest in the project, or hesitation in giving it a hearty co-operation, we detect some misgiving that it may either intentionally or unavoidably conflict with an existing institution or society with which the several professions concerned are already identified. Again, there is an impression that existing corporations, if more life were put into them, or their mode of procedure were altered to meet the wants of our clients, might obviate the necessity for any new departure. On both these points, before matters proceed any further, we think it expedient to offer a few words of explanation, which may tend to remove every objection or hesitation of the kind referred to. We have intended to be perfectly candid all along, and if any misunderstanding has arisen it must be due either to our own want of clearness or to some of our readers suspecting us of designs that we have never contemplated.

First, then, as to the societies with which such an Association as we propose could in any circumstances conceivably clash. The British Association has been mentioned, likewise the Institute of Civil Engineers, the name of the Dynamicables has also been whispered, but, above all, the claims of the Society of Telegraph-Engineers and Electricians have been heard the loudest. Now, the simplest answer in respect of the three largest and most important of these associations is that our scheme more closely resembles the fourth and least formidable of their number—namely, the Dynamicables. Some of our readers may know very little of those gatherings which, under social guise, assemble and meet for purposes which are essentially business-like. Their designation is sufficiently descriptive of their professions; and they have thought and probably found it their interest to unite for concerted action in matters relating to their several callings. They are said to be somewhat convivial; but no objection will be taken to their doings on that score; and, indeed, by way of a beginning, we are inclined to think that something convivial would be desirable for the inauguration of a scheme which, having all the business objects of the Dynamicables, would embrace a much wider circle and vastly augment their powers of usefulness. Nobody has complained that the motives and aims of these electrical and amicable engineers are antagonistic to the well-being of any other society whatsoever; and we distinctly claim for the proposed ASSOCIATION OF ELECTRICAL ENGINEERS that neither would it be open to any such charge. What we desire, in short, is a business or trade combination with which science and scientific societies, except indirectly, have nothing whatever to do.

Such a combination, including members of every electrical manufacture and industry, can never dissociate itself from the scientific sources from which their livelihood springs, any more than the commerce of the world can dispense with the teachings of political economy. But just as ADAM SMITH'S place is not exactly on 'Change, so the place of the scientific electrician is not among practical electrical engineers, though they profit by his researches elsewhere, in the same way that merchants profit by the science of the political economist. And here we may add that we rather deprecate any disparagement of the work and proceedings of this or that society by way of advocating the formation of a new one. We are persuaded that neither the British Association nor any association of that kind could meet the requirements of the case, even if they tried their utmost; and as regards the special and distinct societies already in full operation they have their own work to do, and so far as we know do it very well indeed. Only on one point would we venture to offer criticism in this relation, because it has a direct bearing upon the scheme we are discussing. It will be admitted, we believe, that the proceedings of the Society of Telegraph-Engineers occasionally have been tinctured by what it is no disparagement to call the "commercial" instinct. Consequent on the unprecedented growth of electrical industry during the past eight or ten years the intrusion of a trading element is perfectly natural; and all we have to say about it is that so long as there is no other

Digitized by Google

and more appropriate outlet every learned society will be liable to this reproach. We believe that there would be a distinct gain to the dignity and usefulness of the Society of Telegraph-Engineers if the commercial spirit which sometimes pervades its discussions were kept outside. Possibly the fact that there exists no such provision at present may account for so many important electrical papers finding their way to societies which are not in any special sense identified with electrical research.

After expressing ourselves thus frankly and in full accordance with the great majority of the opinions which have been expressed to us by those chiefly interested, it will, we trust, be perfectly clear that the objects of the proposed ASSOCIATION OF ELECTRICAL ENGINEERS are of a purely business character. To protect their own interests, to promote their own industries, and to discuss the best means of securing these ends, would be the foremost objects of its members—objects which will be none the less easily attainable for being openly avowed. Some of these industries are hampered by legislative restriction, and others by parochial obstruction, to such an extent that nothing short of a compact and powerful organisation will effectually secure free and fair play to their natural and legitimate development. We have not before mentioned the telegraph cable proprietors and manufacturers; but it is not improbable they may see it to their advantage to join in such a combination for the common good. Many dangers threaten these industries, not the least of which is the confiscatory spirit which pervades the political atmosphere in these days, and which is the inspiring motive of the prohibitory conditions imposed upon Electric Lighting enterprise and the establishment of Electric Locomotion. But with or without the co-operation of any particular branch of electrical business, there are a sufficient number directly affected at the present moment to justify them in the formation of an ASSOCIATION OF ELECTRICAL ENGINEERS; and their interests are of sufficient magnitude to induce them, we are persuaded, to combine in some such manner as that we have indicated.

THE LATE PROF. GUSTAV KIRCHOFF.

It is with profound regret that we have to announce the death, on the 17th inst., at the age of sixty-three, of Prof. Gustav Kirchoff, of the University of Berlin. Kirchoff's name is a household word to physicists and chemists alike, from his discovery of the cause of the Frauenhofer lines, or dark lines of the solar spectrum, which formed the foundation of the method of spectrum analysis which was given to the scientific world shortly afterwards in the joint researches of Kirchoff and Bunsen.

He was the author of numerous papers in the scientific journals on various branches of physics, in which he showed himself a skilled experimentalist, as well as a mathematician of the highest order; but, with the exception of his spectroscopic work, his investigations were mostly cast in too mathematical a form to become generally accessible in their original shape.

His investigation of the distribution of electric currents in a system of linear conductors, of which the Wheatstone bridge is a simple example, has become generally known through the text-books, and the original paper offers no special difficulty. His paper "On the Determination of the Constants on which the Strength of Induced Electrical Currents Depends," published in *Poggendorff's Annalen* in 1849, is worthy of special note, as having for the first time furnished a means of determining the resistance of a wire in absolute measure, as was pointed out by Maxwell. His paper "On the Theory of the Flow of Electricity in Submarine and Underground Telegraph Wires" is one of great interest to the practical telegraphist; but it is likewise one which will make very considerable demands on his mathematical acquirements. His investigations of the flow of electricity in wires and superficial conductors and of magnetic induction in iron are electrical classics, and these and other papers, among which we may mention "The Theory of Condensers" and "The Measurement of Electric Conductivity," are both valuable and suggestive, and should not be passed over by electrical students who possess the privilege conferred by a competent mathematical knowledge. A collection of Kirchoff's papers up to date was published at Leipsic in 1882, and we trust that his later investigations may shortly be republished in a similar form.

Kirchoff was an able teacher as well as a great investigator, and his loss will be keenly felt by the students of the Berlin University. Those who have not had the privilege of studying under the great physicist may form an idea of his clear and lucid style of imparting instruction from his "Lectures on Mathematical Physics," published at Leipsic in 1876. On the first appearance of this book the late Prof. Clifford was so struck with it that he proposed translating it for the benefit of English students, and indeed he actually began the work, but was prevented from completing it by the illness which terminated in his death.

G. W. DE T.

A NEW ARC LIGHT DYNAMO WITH AUTOMATIC REGULATION.

We had recently an opportunity of seeing at Messrs. Statter and Co.'s works in West Drayton a new dynamo intended for series arc lighting, and provided with automatic regulation for constant current. The field-magnet of this machine is of the single horse-shoe type, with the yoke in the bed-plate and the poles above. The armature is a Gramme ring 12in. diameter by 10in. long, the core consisting of segmental soft iron plates put together so as to form a continuous annulus according to Joel's patent. The amount of iron both in the armature and field is about the same as would be employed for a glow-lamp machine of equal output, and in this respect the design has the advantage of low magnetic resistance, a strong field, and consequently a fairly high electrical efficiency. It is well known that to obtain a steady light the characteristic of the machine should in the neighbourhood of the working current have a slight downward slope, and this condition can be fulfilled (and in many of the early arc light machines has been fulfilled) by making the magnets of somewhat scant dimensions, and providing an abnormal exciting power, so that the strength of the field should attain its maximum—that is, the magnets become saturated long before the working current is reached. This will give the required downward slope to the characteristic, but at a considerable sacrifice in efficiency and output. In the machine under notice steadiness of the light is obtained in a different way, and the magnets need not be over-saturated, a point of importance both on account of efficiency and first cost.

The regulating mechanism is as follows:—To the support of the bearing on the commutator side is attached a vertical solenoid inserted with the external circuit. The attraction on the core of this solenoid is counterbalanced by an adjustable spring, and the core itself is connected by a rod with a double spring pawl pivoted in a fulcrum which receives a slight horizontal reciprocating motion from a vibrating lever, the lower end of which engages with a pin set excentrically in the end of the armature spindle. Below the pawls are two ratchet wheels, with the teeth pointing in opposite directions. Both these wheels are mounted upon the same spindle, which runs parallel to the armature spindle and controls the position of the brushholder by means of a pinion and segment. As long as the current is of the normal strength both pawls are kept clear of the ratchet wheels, and the position of the brushes remains unaltered, notwithstanding the horizontal oscillations of the pawls. But if the current falls or rises, and thus alters the position of the core in the solenoid, either one

Digitized by Google

or the other of the pawls is caused to come into contact with its respective ratchet wheel, and the brushes are thereby shifted until the current returns to the normal strength, when the pawl is again thrown out of gear.

When the brushes stand on the neutral diameter the electromotive force is a maximum, and it decreases as the brushes are shifted towards the centre of the pole-pieces, being zero when a position at right angles to the neutral diameter is reached. Thus any electromotive force corresponding to the external resistance (number of arc lamps in circuit) can be produced, but this method has the disadvantage of heavy sparking at the brushes unless special precautions are used. To avoid sparking it is evidently necessary to so construct the machine that the number of lines passing through the coils under commutation should be constant for all positions of the brushes, and since this number depends not only on the strength and distribution of the primary field, but also on the secondary field produced by the armature itself, the problem is by no means an easy one. Mr. Statter has attempted a solution by weakening the primary field in those places where it would otherwise be too strong. To attain this object grooves were cut out in the polar surface, so as to increase locally the magnetic resistance of the air space and obtain an even distribution of the lines which are due to the combined primary and secondary field, through an angle of nearly 90 degrees. The exact shape of the grooves was determined experimentally by testing the difference of potential existing between adjacent commutation plates at different angular distances from the neutral diameter. It is evident that these grooved pole-pieces are equivalent to smooth and continuous pole-pieces, the length of which measured parallel to the spindle varies in different points of the circumference; but grooving has been adopted as easier for experiment. In this connection it is interesting to refer to a somewhat similar device adopted throughout for the same purpose by Messrs. Mather and Platt in the large "Manchester" dynamos at the Manchester Exhibition. In these machines the polar surface, instead of being concentric with the surface of the armature, is struck to a greater radius, so as to make the air-space greater at the corners of the pole-pieces than in the middle. This design seems intended to produce an even field and avoid heating in the iron of armature and pole-pieces, but whereas here the magnetic resistance is locally increased near the neutral line, Mr. Statter increases it on the polar diameter, the difference being probably due to the fact that the Manchester machine has a double, whereas Mr. Statter's has only a single magnet. The machine weighs 17½cwt., and is intended for a maximum output of 10 amperes at 600 volts, the speed being 600 revolutions per minute. During our visit the resistance of the external circuit, which consisted of Bernstein glow lamps and iron coils, was varied from 60 ohms to zero, and the regulator appeared to be very sensitive and quick in its action.

THE PROPOSED ASSOCIATION OF ELECTRICAL ENGINEERS.

Out of the mass of correspondence which has reached us on this subject we select the following for insertion. The remainder of the correspondence may be seen at this office. We may add that so far as the London firms are concerned there remains only a very small number who have not already expressed their approval of the movement:—

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I notice with interest that the question of an Electrical Association has been again brought forward. I regret that I have not by me the correspondence now passing on the subject in some of the technical papers, but I wish to take this opportunity before another week goes by of saying that I should personally be extremely glad to see a strong Electrical Association brought into existence, and I think that the action which my firm took rather more than twelve months ago in this matter, associated as we then were with several of the leading electrical firms, is sufficient proof that any such association as the above, if started upon sufficiently broad and impersonal lines, would be sure to be strongly supported. I shall be glad to see from your columns, or from those of your contemporaries, what further action is being taken, as I think that now is a most favourable time for the matter to be pushed forward. I have expressed my opinion personally, as I believe that a large concensus of personal opinion is the first necessary step.

Trusting, therefore, that you will find room for this letter.—Yours, &c., J. F. ALBRIGHT.

Mansion House Buildings, London, E.C.,
17th October, 1887.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: In your last issue you refer to a movement for the establishment of an association for the advancement of the electrical industry. One need hardly bring proofs of the need of an organisation of this kind, sufficient proof being the evidence of the number of attempts that have been made during the last five years by those interested in electrical work to form an organisation to forward their interests. These attempts have up to the present failed, chiefly, I believe, for two causes—first, that they were not universal enough, but confined chiefly to a few leading firms; secondly, that the details were not sufficiently thought out. There is no doubt in my mind that if we are to have an association with such recognised status that it can bring pressure to bear upon Parliament, and that its membership or certificate may be an honourable distinction, and not the mere matter of payment of a fee, it must be an association supported by all, carefully thought out, and with a properly formed organisation and a proper and efficient staff. As yet the whole scheme is floating in the air, and needs a definite shape. I would suggest that the matter be taken up by someone known to be unbiased, say, the representatives of the technical press, that a meeting of those interested in electricity be called at the Cannon-street Hotel, and that, after discussing the matter, a representative committee be elected to draw up a report to be published and laid before a subsequent general meeting, showing the different methods in which the scheme might be carried out, and pointing out their relative advantages and disadvantages. At this subsequent meeting the scheme might be settled upon and a permanent committee appointed, in which all degrees of those interested should be fairly represented, and a definite line of policy laid down, so that one might have an opportunity of seeing whether it is worth while joining it.

In conclusion I may give a list of points, a few of which it may be worth while for the association to take up:—

1. To bring pressure on Parliament in such matters as Lightning and Tramway Acts.
2. To remove legal restrictions and obstacles to the growth of the industry generally.
3. To aid in the opposition to vested interests where opposed to electrical work.
4. To establish public confidence, especially in the financial and commercial world.
5. As far as possible, by inspection or otherwise, to compel firms to do good work.
6. To approve of articles and methods (hall mark).
7. Maintenance of prices at a fair level.
8. To act as a registered authority for tests.
9. The conferring of certificates, both upon individuals and upon articles.
10. The comparison (wire gauges), issuing and certifying of standards.
11. The minimising of and dealing with fire and life risks.
12. Registration of applicants for employment.
13. Registration of "black sheep."
14. Protection of the trade financially.
15. Stamping out of blackmailing and similar systems.
16. Arbitration between firms and individuals.
17. To give opportunities for conferring together on the above subjects.—Yours, &c., F. L. RAWSON.

TO THE EDITOR OF THE ELECTRICIAN.

DEAR SIR: We observe with pleasure that the proposal to establish an association for the discussion and development of practical and commercial electrical engineering is likely to become an accomplished fact.

We shall be glad to support such an association, and to assist, as far as possible, in its formation.—Yours faithfully,

TASKER, SONS AND CO.

New Station-road, Sheffield, October 17, 1887.

Industries, of the 14th inst., contains the following remarks on the subject:—

PROPOSED ASSOCIATION OF ELECTRICAL ENGINEERS.—The hint thrown out a fortnight ago by our contemporary, *The Electrician*, which recommended British electric light engineers to follow the example set by their American colleagues, has been favourably received by professional men both in London and the provinces. American electricians have, with a view to further their common interests, established an electric light convention; but on this side of the Atlantic there exists at present no similar organisation, although there are two societies for the furtherance of electrical work. The one is the Society of Telegraph-Engineers and Electricians, which was originally started by telegraph men, but has of late years concerned itself to a considerable extent with the scientific aspect of heavy electrical engineering; the other is the society known as the Dynamicables, which started with the intention of combining the social, scientific, and commercial elements in the profession, but which, attempting too much, has not been very successful. The proposed association of electrical engineers would concern itself more especially with the commercial, legislative, and administrative portions of the electric light business, leaving the scientific part to be dealt with as hitherto by the Society of Telegraph-Engineers and Electricians. That some such organisation has plenty of scope must be patent to all who have of late years studied the slow growth of the electric lighting industry in this country.

The current number of the *Engineer* contains the following:—

AN ASSOCIATION OF ELECTRICAL ENGINEERS.—It has been proposed that an Association of Electrical Engineers should be formed with a view to founding a corporate body whose functions should be concerted action in all matters in which those are interested who are engaged in the manufacture of electrical engineering machinery, apparatus, and appliances, and in general with the commercial applications of electricity, and also as a means of providing for the desirable frequent meeting of all electrical engineers with the view of discussing subjects of current or particular interest, business questions, or those upon which it is desired that the opinion of the body should be taken with a view to influential action in Parliament or elsewhere. *The Electrician* has called particular attention to the subject, and already it appears that a considerable number of electrical engineers have written in support of the proposal, and of the necessity for an association which shall take the place of a business association instead of one of a scientific character. At the meetings of the Institution of Civil Engineers the trade side of matters is properly kept out as much as possible, and the society with the long name requiring a fount of type to print it, namely, the Society of Telegraph-Engineers and of Electricians, does this also to a great extent. There are other societies, such as the Iron and Steel Institute, whose discussions and proceedings deal with business questions much more; but what is required isan association which provides the means for carrying out the objects already mentioned, and of providing for frequent meetings at which men can, as at a social gathering, or in body, discuss questions set forth in a programme upon any matter which is exercising the minds of electrical machinery makers, designers, apparatus makers, or those who are engaged in installation work or provision of *matériel* for it. The matters most occupying attention, or upon which discussion may be usefully directed, can often be put before a meeting in ten minutes' speaking, and by men who cannot get the time to prepare formal papers. A properly and vigorously conducted development of the society known as the Dynamicables, but with a more business name, is what is required.

[In Mr. J. V. Money-Kent's letter, which appeared in our last issue, by a slip of the pen in the tenth line, the writer expressed the reverse of what he had intended to convey. The sentence in question should have read that the Society of Telegraph-Engineers "is *not* likely to trouble itself about commercial questions."]

ON THE LOCALISATION OF A COMPLETE FRACTURE IN A SUBMARINE CABLE BY BRIDGE MEASUREMENT TO INSTRUMENT ZERO.

BY A. E. KENNELLY.

(Concluded from page 482.)

We will now examine the accuracy of the method embodied in these equations (22) to (36). Of course, if the premises assumed in the formation of equations (16) to (21) are true, then the distance of a fracture could always be calculated with certainty in this manner. The premises require, besides accuracy of the balances and the instruments establishing them, that the resistance f of the fracture shall vary inversely as the square root of the traversing current, and also that E, e, and η shall remain constant through the three measurements.

As regards f, we know that it does not vary strictly according to the inverse square root law when the exposed surface of the conductor at the fracture is small, for reasons that appear by experiment to be connected with the mechanical insulation of the exposure by accumulating gas at different rates of evolution. Thus it unfortunately happens that when the exposed area is less than a certain limit, which may be roughly stated at half a square centimetre, the rate of variation in f descends from the inverse square root towards the inverse cube or fourth root of the traversing current. Consequently, on this ground alone, the accuracy of the method is confined to cases where the exposure has such dimensions that the gas evolved on it escapes unimpeded, and that its resistance is steady to any steady testing current from the zinc-pole of the battery.

By selecting a suitable battery we can depend upon the constancy of E within close limits, but e and η are, of course, beyond control. If e varies, then, by sufficient repetition of x, y, and z, it may be possible to eliminate the effect of this variation on the result, as e is clearly independent of c. The case is, however, different with η, which we know to be a function of c, increasing as c increases, but at a rate which we have not been able to assign. In many experiments we have found that η varies approximately as the direct fourth root of c, but the rate of variation appeared to differ not only with different exposures, but at different points in the range of current strength through the same exposure. Thus it generally appears that when c is small η increases faster than the cube root of c, but that as c increases in value the rate of increase in η diminishes until it falls below the fourth roots, and, consequently, the assumption in the generating equations (16) to (21) that η is constant involves an error in the result.

These two errors—one of f's deviation from inverse square root law and the other of η's inconstancy—unite in reducing d and D; and the question arises, what values should be assigned to n and m that the error in the result shall be a minimum?

Equations (25) to (29) show that the same sign of error in d and D introduces errors of contrary sign into the calculation, and that an error in d vitiates the result more than the same error in D. Thus an error of δ in both d and D affects the result by formula (26) with $3{\cdot}5\delta$, formula (27) with $1{\cdot}13\delta$, (28) with $1{\cdot}67\delta$, and (29) with 7δ, so that it is advisable to make m large and n small, formulæ (26) and (27) giving the best results in practice.

That the variation of η may have less influence on the

Digitized by Google

results it is advisable to make E, the testing E.M.F., conveniently large, and not to employ very feeble currents.

We will now state one or two practical examples of the method.

Experimental case with exposure of about 2 sq. cms. of cable core conductor in circuit with resistance only. E approximately 45 volts. Zinc to line $\frac{1000}{1000}$ ($\lambda = 1$).

With 2 milliamperes to line ..... $x = 1450\omega$
" 8 " " " ..... $y = 1305\omega$ $(n = 4)$
" 18 " " " ..... $z = 1270{\cdot}7\omega$ $(m = 9)$

Here $d = 34{\cdot}3$ and $D = 179{\cdot}3$, so that by formula (26)

$$l = 1270{\cdot}7 - 4 \times 34{\cdot}3 + \frac{179\,3}{2} = 1223{\cdot}2\omega,$$

and by direct bridge measurement l was 1226ω.

When the exposure was small, however, such a degree of accuracy was seldom met with. The following, for example, was a case with a small exposure :—

With 3 milliamperes to line..... $x = 795$
" 12 " " " ..... $y = 504{\cdot}9\omega$ $(n = 4)$
" 27 " " " ..... $z = 434{\cdot}6\omega$ $(m = 9)$

Here $\lambda = 1$, $d = 70{\cdot}3$, $D = 360{\cdot}4$, and $\therefore$ $l = 333{\cdot}6\omega$. The actual value of l by direct measurement was 350ω.

The following results were obtained with a broken cable in which the fracture was recovered the same day, and the area of exposure found to be approximately 0·6 sq. cms. 225ω distant ($l = 225$). In addition to a series of readings to false zero, three sets and a series were observed to true zero as follow :—

20 Calland cells. 100/1000 Zinc to line.

With 6 milliamperes to line $\frac{x}{10} = 436\omega$.
" 24 " " " $\frac{y}{10} = 290\omega$. $n = 4$.
" 54 " " " $\frac{z}{10} = 260{\cdot}5\omega$ $m = 9$.

Here $d = 29{\cdot}5\omega$, and $D = 175{\cdot}5\omega$, and by (26) $l = 230\omega$.

SET No. 2. *Similar conditions :—*

With 5 milliamperes to line $\frac{x}{10} = 460\omega$.
" 20 " " " $\frac{y}{10} = 298\omega$. $n = 4$.
" 45 " " " $\frac{z}{10} = 264$. $m = 9$.

Here $d = 34$, and $D = 196$. $\therefore$ $l = 226$.

SET No. 3.

With 3·5 milliamperes to line $\frac{x}{10} = 539$.
" 14 " " " $\frac{y}{10} = 319{\cdot}7$ $n = 4$
" 56 " " " $\frac{z}{10} = 257{\cdot}3$ $m = 16$

Here $d = 62{\cdot}4$ and $D = 281{\cdot}7$ and by formula (28) $l = 226$.

The following series was then taken :

Milliamperes Current to Line.	Balance Reading ÷ λ.	Milliamperes Current to Line	Balance Reading ÷ λ.
50	259·7	10	347 5
45	262·8	9	359·0
40	265 7	8	374·0
35	269·8	7	393 0
30	275·5	6	419·0
25	283·0	5	457·0
20	294·5	4	540·0
15	312·0	3	589·0
		Check 50	259·9

Various combinations can be taken from this set and solved by formula (25). If selected so that m and n are small, the results will be found to have large errors in some cases, but by selecting n and m more judiciously greater accuracy will be obtained.

We have thus seen that the law of inverse square roots can be applied to the elimination of f in measurements to true as well as to false zero. The false zero method enables a complete series of observations to be taken in such a manner that pairs of readings may be selected from various points in the range, and the values of l so found serve to check the result with greater facility than a series of true zero observations can under the same conditions afford. The errors in the result, owing to any deviation of f from the law, or to the inconstancy of η, are also less in the false zero method than in the other, for algebraic reasons. On the other hand, the true zero method is not limited like its competitor to a current range of 25 milliamperes, for the reason that it measures the true value of η, which the false zero method applied to cables can never do, since by the time the electrostatic discharge on removing the testing battery has ceased, η has always fallen considerably, consequently the current through the galvanometer while the battery is removed is not the current that would be produced by the full $\pm(e \pm \eta)$ actually in the cable during the testing current's flow. Therefore, there can be little doubt that if the laws which connect the increase of η with the increase of e could be ascertained and applied, it would be possible by true zero formulæ like those detailed above to localise a large exposure fracture with great accuracy. The fact that these formulæ have already served to fairly localise such exposures both experimentally and in the practical instance mentioned, is perhaps, on a due consideration of their intricacy, a crucial test of the truth of the inverse square root laws.

In conclusion, it may be pointed out that formula (7) supplies a simple and convenient method of measuring to true zero the apparent conductor resistance of a perfect cable containing earth current E.M.F. The ordinary method of doing so is by reversing the battery, and observing x and y with opposite poles to line. The formula for solving l is then somewhat lengthy. If, however, we can by any simple means double the unreversed testing current to line either by doubling the testing E.M.F. (compensating for extra battery resistance) or by the use of ρ in the figure, we obtain by the Mance formula $l = y - d$ strictly, or if the form be preferred,

$$l = 2y - x \quad . \quad . \quad . \quad . \quad . \quad . \quad (37)$$

and the case taken from Sir Henry Mance's paper, solved above after equation (11), is coincidently an instance of this.

SUMMARY.

The method of localising a fracture described above is based on the laws of inverse squares connecting the current strength surfaces and resistances of exposures in sea water. It consists of measuring the resistance of the fracture and cable up to the fracture by bridge to true zero, with the zinc pole of the battery to line, three times in succession, with a different and definite strength of current to line each time. The best ratios of current strength so to employ are given at equations 26, 27, and 28. From the three balances thus obtained the distance of the fracture can almost be calculated mentally. As an example, taking the case of equation 26, the current strengths sent to line in the three successive measurements are as 1, 4 and 9. The balance readings—always using zinc to line—will be found practically to be in descending magnitude, the first greatest, the third least. Then the distance of the fracture from those readings would be the third added to half the difference between the first and third, reduced by four times the difference between the second and third.

It is not pretended that in every case the distance of a fracture can be exactly calculated in this way. Like the false zero method of determination based on the same laws error cannot be excluded, and each method has its own advantages and its own particular liability to error, as compared above;

Digitized by Google

but by care these errors may, in most cases that occur practically, be so minimised that their effect on the calculated result may be neglected, and with fractures of considerable exposed area will in any case be small.

The relative superiority between the "false-zero" and "true-zero" methods must be left to general experience and opinion.

LITERATURE.

Dictionnaire d'Electricite et de Magnetisme. By E. JACQUEZ. New Edition. [Paris: C. Klincksieck.]

A revised and enlarged edition of M. Jacquez's "Dictionary of Electricity and Magnetism" has made its appearance. The new edition contains more than 400 additional terms, and the whole work has been brought fairly well up to date. So far as we have yet discovered the collection errs—if it be an error—on the side of inclusiveness rather than exclusiveness. At any rate, we have always succeeded in finding the term for which we have made search; and, on the other hand, have come across many terms which we should certainly never have made inquiry for. This remark applies particularly to phrases used in connection with telegraphy, such, for instance, as "Changement de service," "Remise de service," "Reprise de service," "Livre de remise de service," all which phrases refer simply to the transfer of duty amongst the clerks in a telegraph office. It would, however, give a very unfair idea of the actual value of this work to allow it to be supposed that it is chiefly made up of such phraseology as the above. On the contrary (as, in fact, we have already intimated), it contains a well-nigh exhaustive list of the technical terms and phrases employed both in the theoretical and applied sciences of electricity and magnetism. Each term is connected with the English and German equivalent, and a sufficient explanation or amplification is given in the French. The aim is to provide a dictionary and not an encyclopædia, but in very many cases the treatment is sufficiently full to be of some value to the student who is in search of instruction. This remark is, however, only of partial application. "Magnétisme" is, for instance, dismissed in four lines, while "Magnétisme Terrestre" occupies more than a page. The work concludes with a collection of German-French and English-French synonyms. We might suggest to the author the propriety of including in a future edition a set of tables of resistances, &c.

STANDARD LAMPS.*

BY A. VERNON HARCOURT.

At one of the meetings of this section last year a lamp, devised by the author, for producing a constant amount of light was shown and described by Mr. W. S. Rawson. The lamp now exhibited served the same purpose, but is simpler in principle, more easily adjusted, and less affected by draughts. It consists of a glass reservoir with tubulure and stopper of the form and size of a large spirit lamp, mounted on a metal stand provided with levelling screws. The wick could be turned up and down in the usual manner within a long tube attached to the body of the lamp. Around this tube is a wider tube 100 by 25 millimetres, and the two being joined together above and below by flat plates constitute the burner of the lamp. When the burner becomes warm by conduction of heat from the flame, the pentane which arises from the wick volatilises and burns at a considerable distance above the point to which the wick is turned. Thus, the size, or texture, or quality of the wick does not affect the flame. Round the burner and the lower part of the flame is another cylinder, opened at both ends, and contracted above the burner to the tube, 20 millimetres in diameter and in length. A similar tube formed the lower part of an upper opening, which was enlarged above to a diameter of 25 millimetres. The upper part of the flame was concealed by this lamina, excepting where a narrow slot, 10 by 3 millimetres, on each side showed the tip of the flame, and enabled its height to be regulated. Through the interval between the two laminas the flame shines, and the light which it gives is the same whenever the top of the flame is visible through the slot, whether towards the lower or the upper end. The two laminas were attached together by two curved metal bands sufficiently removed from the flame on either side not to affect it. The attachment of these bands to the lower lamina was adjustable, so that the opening through which the central parts of the flame were seen might be made larger or smaller. By means of small cylindrical blocks whose thickness was actually gauged, the width of the opening might be set either to that which the light emitted or one candle, or if a greater or a smaller light was desired, a candle and a half or half a candle, the width of the connecting bands was half that of the tube which surrounds the flame. When these bands were placed in a plane perpendicular to the bar of the photometer point, midway between their edges and at half the height of the flame might be taken very approximately as that from which the light radiated. The liquid with which the lamp is fed is pentane in the manner already described from American petroleum.

* Abstract of a paper read before the British Association Meeting at Manchester, September, 1887.

ON ELECTRIC STREET CARS, WITH SPECIAL REFERENCE TO METHODS OF GEARING.*

BY A. RECKENZAUN, C.E.

Scarcely nine months have passed since your esteemed president, Mr. T. C. Martin, presented a paper on "Electric Street Cars" to the American Institute of Electrical Engineers. I have read this excellent paper with interest, and I have learned a great deal from it, as also from the discussion which followed. Mr. Martin compiled some very important statistics regarding the number of horse cars in actual use in the United States, and he computed them to number 25,000, for the propulsion of which no less than 120,000 horses are requisite.

These figures filled me with wonderment and surprise, and when I read further on that over 20,000 of these noble animals are rendered useless every year with overwork in street railway service, I felt it to be the duty of every engineer, electrical or mechanical, to assist with every means in his power in the emancipation of the horse from such cruel service. The percentage of loss given in the paper referred to agrees closely with our European experience. We know that the natural life of a street car horse is reduced to about four years, although it never works more than four hours a day. It seems barbarous, therefore, to employ animals for such purposes; yet until recently no economical substitute could be found. Steam, compressed air, gas and spring motors have been tried and found inefficient. Improvements may be made in one or more of these, but at the present moment the field of enterprise is entirely open to the cable and to electricity. There are over eighty miles of cable roads in operation in the United States, more than half of which have been laid down within the last five years, and there are indications that further and rapid progress will be made with this mode of traction, particularly in hilly districts, where it is impossible to apply self-propelled cars owing to the want of cohesion between the wheels and rails when the angle of repose is approached.

On ordinary streets with gradients of not more than 5 per cent., electric traction will doubtless be more economical and far more convenient than cables, for well-known reasons. Not only is the first cost of construction far cheaper than the cable and its conduit, but the efficiency of the electric system is much greater.

It is admitted that on cable tramways some 70 or 80 per cent. of the total available power is consumed in dragging the cable itself, leaving a maximum of 30 per cent. for moving the cars, whereas with electric transmission over 50 per cent. can be utilised, as will be seen by the following figures, which I have obtained from experiments on the electrical railway at

* Paper read before the American Institute of Electrical Engineers, New York, Sept. 20th, 1887.

Digitized by Google

Frankfort, in Germany. This line is worked by the overhead conductor system. Its total length is four and one-tenth miles, double track and grooved rails. The entire circuit of the conductor is eight and one-fourth miles long, and its electrical resistance was calculated to be 1·6 ohm.

EFFICIENCY AND WORKING COSTS.

During the experiments referred to, two cars were propelled at a speed of seven and a-half miles an hour; one of these cars had an electric motor, and the other was an ordinary car attached to the first, and the entire weight was ascertained to be 8·35 tons, including passengers. Electrical measurements were taken from the dynamo at the power station simultaneously with those on the car. The rails were in their usual dirty condition. When running on the level road the energy used on the cars was 3·87 horse-power, and on the generating dynamo 6·47, giving an efficiency of 59·82 per cent.; when travelling up a grade of 1 in 45, the motor gave 8 horse-power and the dynamo 13·5, which again corresponds to 59 per cent. of the available electric energy. These measurements do not include the losses in the dynamo and motor, but it must be remembered that only two cars were on the road, whilst the capacity of the plant at the central station was sufficient for 14 cars. With 12 cars running under the ordinary circumstances of traffic, the steam engines were indicated, and this showed a maximum of 164 horse-power, consuming two and three-fourth tons of coal per day of 15 hours, or two and one-half pounds per indicated horse-power per hour. Reduced to car miles, the weight of coal came to 7·5 pounds, which, at three dollars a ton, would cost one cent per mile run.

The Frankfort electric railway has carried over 3,000,000 passengers since its opening in April, 1884. The working expenses in the year 1886 amounted to $24,904, including the following items:—

Salaries of directors, superintendent, engineers, electricians, conductors, drivers, firemen, and labourers	$13,615
Repairs of roadway, rails, cars, machinery, and buildings	5,088
Fuel (coal and kindling wood)	3,955
Oil and waste	831
Lighting and heating of buildings, lighting of cars and streets	1,415
	$24,904

The rolling stock consisted of 14 cars, all of which were used on Sundays and holidays, but only eight cars were usually running on week days. If we take an average of 10 cars, then the entire expenses would amount to $6.82 per car per day, but not more than one-third of this, or $2.27, can be reckoned for the item of traction, which should only include wages of engineers, electricians, firemen, cost of coal, oil, and repairs to machinery.

There are about a dozen electric railways in successful operation in Europe, some more extensive than the one I have just described, some smaller; but this one in Frankfort is worked at a greater expense than any of the others I know of; it has been in continuous use for nearly three and a-half years, and I thought that by giving you detailed and exact figures of *one* line, I would serve your purpose better than by attempting to crowd a few generalities of all our electric tramways into the small compass of a short paper. You can take this as a safe standard of comparison with other systems of street car traction.

It will be observed, with justice, that the dynamos and motors of the Frankfort line, which was projected more than four years ago, do not yield as high an efficiency as more recent machines. This would leave us another margin. It is well to have a margin in all our estimates, for there is nothing that retards the progress of a novel enterprise more than exaggeration of facts, or statements which cannot be fully borne out in practice.

Some people are apt to base their calculations and estimates upon theoretical conditions. We should never assume perfection in the case of street railway tracks, but, on the contrary, we ought to adapt ourselves to the roughest of the rough in order to succeed.

TRACTIVE FORCE AND MECHANICAL RESISTANCES.

We know from experience that street rails which are exposed to dirt, grit, stones, and the like, offer a resistance of at least 20 pounds per ton with the wheels in motion. Taking the loaded car at six tons, and the speed at six miles an hour, we have to exert 1·92 horse-power at the driving wheels, neglecting friction of gearing and losses in the electric motors. On narrow grooved rails, as used in England, we allow a tractive force of from 25 to 30 pounds per ton. These high resistances are readily accounted for when it is considered that the flanges of wheels frequently take a bearing on the dirt in the grooves; at the same time the wheel tyres may roll on the suface of the rails, when a regular grinding action is produced. Furthermore, it occurs frequently that one wheel is running on its proper bearing surface, whilst the other, belonging to the same axle, has its flange touching the bottom of the groove, when by virtue of different circumferential velocities, additional friction is introduced. Sometimes the rails are a little out of gauge. All these points increase the tractive force requisite with grooved rails. Here in America you have few, if any, such rails, consequently the facilities are superior; but your rails are not so strong as those used in England and on the Continent of Europe, and the foundations are less substantial. The joints are also somewhat irregular, and these faults render the motion of a car very unsteady. A ride on some of the roads in Philadelphia reminds one of a voyage on the ocean when the sea is a little rough. Then you crowd very often 70 passengers into a car which is supposed to hold about 30. All these circumstances compel us to provide plenty of power in order that every obstacle can be overcome.

The force necessary for starting a car is of course much greater than the force required for maintaining a uniform speed, and experiments show that this initial effort amounts to three times and even four times the tractive force of the car in motion. In dry weather, on curves of 50ft. radius, the resistance to traction is doubled, and on those of 35ft. radius trebled; but when the rails are wet this resistance, due to curvature, is considerably reduced. With a short wheel base, or, better still, with small trucks or radiating axles, the motion on curved rails is very much easier.

(To be continued.)

THE LEVER DYNAMO.

This machine differs from others in that the armature has projecting teeth which revolve in grooves in the pole-pieces.

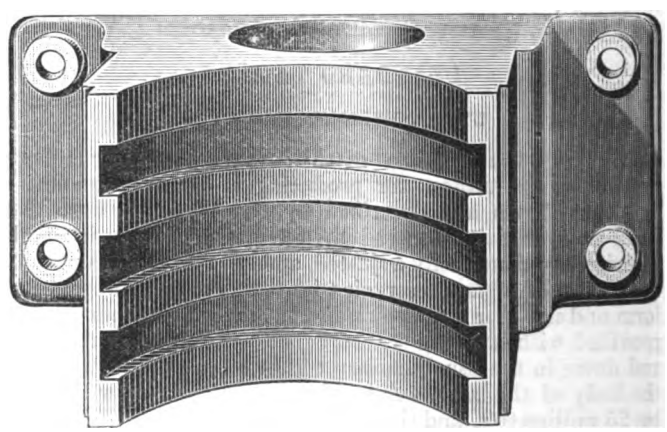

FIG. 1.—Grooved Pole-piece of Lever Dynamo.

Fig. 1 shows a grooved pole-piece and Fig. 2 the armature. By thus increasing the surface of the iron of the armature the magnetic resistance of the air space is evidently reduced. The grooves in the pole-pieces are made in the same machine which bores them out. Fig. 3 shows the dynamo complete. It is of compact construction, and occupies little floor space. The field-magnets are massive, and we are informed that there is an entire absence of sparking at the commutator with hardly any lead at the brushes. The dynamo is also said to have a high efficiency of conversion.

The first machine built in accordance with this design was tested at Messrs. Blakey and Emmott's works, Halifax, with

Digitized by Google

the result that at a speed of 1,550 revolutions an E.M.F. of 210 volts was obtained with a current of 11 amperes. The resistance of the armature is 1·31 ohm, resistance of field-magnet coils ·84 ohm. Mr. Lever informs us that he hopes to reduce the armature resistance very much in later machines of this type.

THE LEVER ARC LAMP.

The new type of lamp illustrated in the adjoining figure has a solenoid in lieu of the electro-magnet employed in the older type. There is no glycerine required in this lamp.

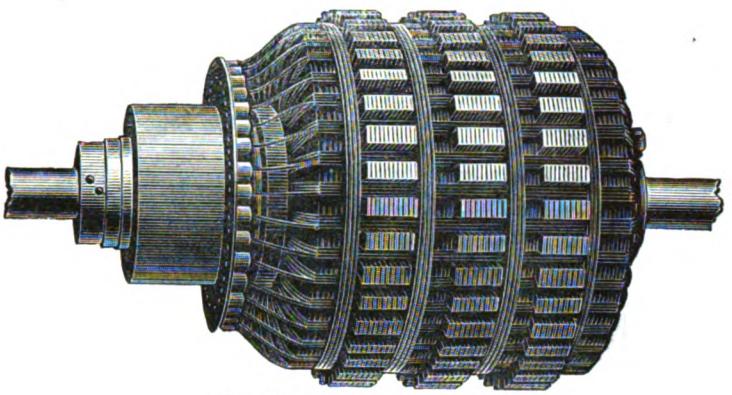

Fig. 2.—The Lever Armature.

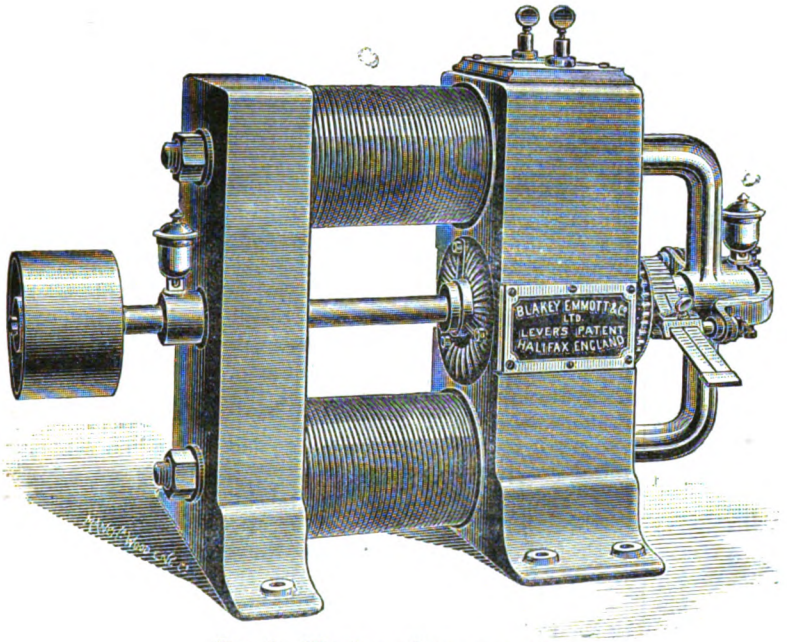

Fig. 3.—The Lever Dynamo, complete.

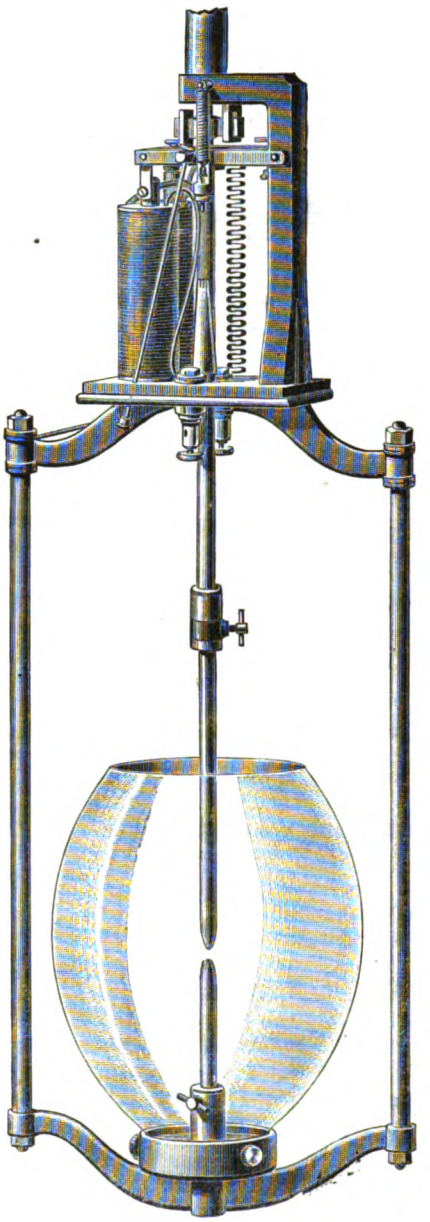

The Lever Arc Lamp.

The solenoid plunger fits nicely but easily in the brass spool of the solenoid, and when it is attracted there is a slight compression of the air within the spool. A brass link is connected to the plunger and lever. The lever is free to oscillate on a pin fixed in the upright arm of the top frame. A spring, adjustable by a nut on the lever, and held at the top by another pin in the frame, draws up the lever in its normal condition. The hollowed clutches held by its arms in two sleeves, one fixed to the frame and the other movable with the lever. The upper carbon holder slides freely through the clutch and through bearings in the frame, and is protected by an outer brass tube screwed on to a bush cast with the lamp frame, by means of which the lamp is suspended. The thin copper brush, shown in the illustration, transmits the current to the upper carbon holder. Mr. Lever assures us that in working it is only with the most careful attention that the feeding can be seen, so gently does the upper carbon descend, and the lamp will give a very steady light with cheap American carbons, thus reducing the cost of working to a minimum.

The automatic "cut-out" is very simple. It consists of an electro-magnet, shown on the farther side of the solenoid, and wound with two layers of coarse wire, one end being connected to the core of the magnet, which is insulated, and the other to the resistance strip and to negative terminals. A flat headed iron screw, passing through the lever, comes over the magnet-pole, but does not touch it until the solenoid pulls the lever down past the feeding point, which it would do if the upper carbon holder sticks. In this case the solenoid would draw down the lever until the flat headed screw made contact with the magnet core. The lamp would then be cut out, the current passing through magnet-core, its two coils and the resistance to negative terminal, and the cut-out magnet would hold down the lever so long as the lamp failed to feed. If the carbons make contact again the spring overpowers the cut-out magnet, draws up the lever, and the arc is re-struck. The lamp is automatic in all its functions. The small slanting brass wire on the lever is used in trimming the lamp when the case is on. By pulling the little knob on the left-hand side the lever is lowered and the upper carbon holder released.

CORRESPONDENCE.

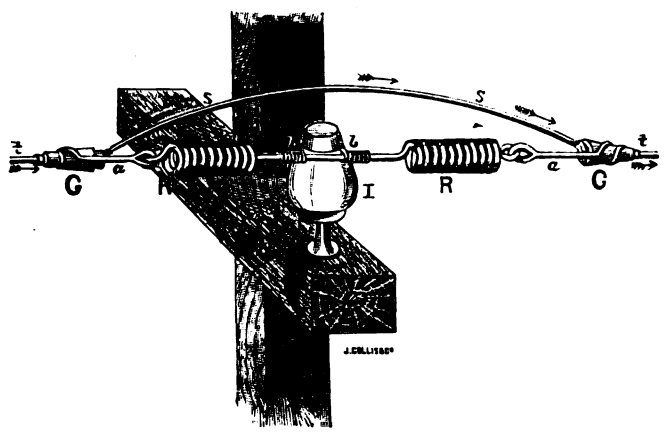
SPRINGS ON TELEGRAPH WIRES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: To-day my attention has been drawn to Prof. Perry's letter in your issue of the 30th ult. On the 1st ult. I entered at the Patent Office my invention entitled "Flexible Supports for Telegraph Wires." Half a week later, singularly enough (having, as he has since informed me, for some time worked at the subject), Sir Frederick Bramwell suggested this thing at Manchester; and those electrical and engineering weeklies which published my invention in their list of patent applications published in the very same issues a report of the B.A. meeting at Manchester, with Sir F. Bramwell's suggestion and the discussion ensuing.

On reading this report I at once wrote Mr. Preece and Sir F. Bramwell, informing them of my patent application, over which I had been long busy.

The precise method suggested by Sir F. Bramwell is included in my specification amongst a variety of methods effecting the same objects. But the complete regulator preferred, after careful consideration of the electrical, mechanical, and practical requirements, is, as you will see from the enclosed sketch, different from the method suggested at Manchester, and not open to the objection urged against the latter by several speakers, viz., "that it necessitated two insulators."



R R, spring regulators. G G, automatic self-gripping clamps. The grip is caused by the counter tension of the line wire *t t* and the spiral clasp anchors *a a*, while the line wire *s s* is not in tension, but bent sideways and upwards so as to stand free of the insulator I, to which the regulator is bound by the wire *b b*. The rubber tubing and the flexible motion of the points of attachment G G prevent possibility of the wire chafing.

NOTE.—The electric current takes the path indicated by arrows, the wire being insulated by vulcanised rubber tubes where clasped by the clamps G G. Any leakage at G G passes through R R, and is again insulated by I, so that the only leakage which can occur at I is the *leakage of the leakage.*

I use the present single insulator, unaltered, as it stands; and, at the same time, while protecting the wire from storm stresses beyond its strength, its insulation is greatly improved, so that a wire supplied with these regulators is a better conductor than a wire of much larger gauge without them. Also, by this same method of suspension, I entirely prevent that transverse chafing of the wire at the insulators which now causes continuous and much more insidious and universal destruction than the temporary damage wrought by occasional storms.

I was glad that Mr. Preece at the B.A. meeting, as soon as he got to understand what Sir F. Bramwell meant, promptly withdrew the objection he at the outset advanced. I am likewise glad to observe that Prof. Perry in his letter withdraws to a large extent from the opposition he offered to the suggestion at Manchester.

The subject is one on which the best trained minds are extremely liable to err at the first blush, but which on closer scientific investigation leads to one irresistible conclusion, viz., that, for *copper* lines regulators are necessary and advisable, because at an *extremely moderate cost* they can be so applied as to vastly improve insulation and entirely prevent chafing, while doubling the strength and therefore quadrupling the life of the wire against storm stress.

Reference to meteorological records over a sufficient range of time will, I believe, prove that the frequency of storms is in inverse ratio to the squares of their intensities. Thus by doubling the elasticity of the line (as the regulators unquestionably would do) the periods at which overstraining storms may occur are placed at four times the interval of the periods at which overstraining storms (of half the intensity) do occur under the present system of hanging up the lines.

Prof. Perry is quite right in his contention that the springs suitable to regulate iron telegraph wires of 7½ B.W.G. would be too heavy and costly to come into general use. But iron telegraph wires are doomed to give place to copper, and the sooner they do so the better. It is not for iron but for copper wires the regulators prove suitable and also economical. These regulators will enable the 100lb. copper wire to fulfil all requirements much better than the 150lb. copper wire without regulators.

As to the tenacity and extensibility of the spring, they must be of course equal at least to the tenacity and extensibility of the line wire.

In dealing with copper lines it is quite easy, by increasing the number of coils of regulator spring, to make its extensibility considerably greater than that of the line wire without rendering the regulator unduly clumsy or costly. But by introducing too much extensibility into the regulator we should render the dip of each span inconveniently great during storms, and this is the consideration which renders it prudent to limit this extensibility. In plainer English, it is only by slacking down the span the regulators save the wire from excess of storm stress. But you may slack it down too much. During storms of wind the lines not only oscillate like pendulums with the alternations of wind force, but they are also liable to skip, writhe, and *flap*, in some small degree like flags or pennons, and to become entangled with one another. I believe the entanglement would not occur if all the wires on a span were hung exactly the same dip. But in the present practice of linesmen, variations and inequalities of dip occur from a variety of causes, but mainly from having copper and iron wires hanging on the same posts. The copper is of course almost inevitably tighter in winter and slacker in summer than the iron. Thus unequal dips occur which are during storms oscillating at unequal times, like pendulums of unequal lengths; hence entanglement and confusion. Telegraph engineers have already learnt to avoid one fruitful occasion of entanglement—viz., joints in the line wire, or projections of any kind, occurring at midspan instead of at insulators, and by such avoidance they have already largely reduced the evil. By adopting regulators they would secure uniformity of dip, and so avoid the chief remaining cause of entanglements. But the extensibility of the regulators must be limited to that of the line wire or something not much greater, or, so far as the mere question of entanglement goes, the cure might prove worse than the disease.

Prof. Perry has alluded to the relationship between the weight of springs and their elasticity; and I may be permitted to add that while the extensibility of helical springs is directly as the number of their coils, and the diameter of the spring and the gauge of its steel do not therefore determine the aggregate elasticity of the spring, yet this diameter and gauge do determine the elasticity of each particular coil—that is to say, the diameter and gauge settle the *unit* of extensibility, while the number of coils determines the number of units composing the aggregate stretching capacity of the spring. The elasticity of each coil is, in fact, as the cube of its mean radius, and (for round steel) inversely as the fourth power of its gauge diameter, and the ultimate tenacity of the spring is as the cube of its gauge diameter and inversely as its mean radius of helix. I make the tenacity of my spring regulator about 18 per cent. greater than that of the copper line wire, to allow for the more rapid corrosion of steel than of copper. The limit of elasticity occurs at nearly half the breaking stress. Steel of considerably less tenacity than 50 tons per square inch may suitably

Digitized by Google

be used in the construction of regulator springs for copper wire lines.

At 22deg. F., a copper line wire weighing 100lbs. per mile, and strained up to one quarter of its breaking stress, in a span of 100 yards, if so coated with snow as to present to the wind twice as much resistance as the naked wire offers, will be unable to endure without overstrain a greater wind pressure than 7lb. per square foot. But the same line wire under precisely the same conditions will, if fitted with a regulator of less than 1¼lb. weight, including its appendages, endure 13lb. per foot wind pressure without overstrain, and by doubling the number of coils (which would not be equivalent to doubling the total weight) the regulator will enable the line to sustain, under same snow-covered conditions, a wind pressure of 17lb. per foot without overstrain. I recommend the shorter spring as meeting best all practical needs.

In support of what Prof. Perry has advanced I may, in conclusion, point out that if the calculator in preparing tables of dip and stress of wire catenaries at various spans and temperatures were to deal only with the expansion of the wire and neglect its elasticity, his results would grossly exaggerate the differences between winter and summer dip and stress, for an infinitesimal percentage of stretch due to elasticity makes a most material change in dip, and consequently in stress. For example, a copper wire, weighing 100lb. per mile, and having a normal length of only 299·7134ft., when stretched across a span of 300ft., will have a dip of 2·583ft., and will have a catenary length of 300·0593ft. Its stress at insulators will be 82·51lb., and owing to that stress it will have stretched 0·3459ft. Thus, we see a stretch of only $\frac{1}{11}$ per cent. causing a dip of no less than 2·533ft. This stretch will be due to this stress at any time of the year, irrespective of temperature. But, now, after the wire has been so fixed up let the temperature rise, say, 54deg. F. What will happen? The change of temperature will cause an expansion of 0·162ft. in the length of that copper wire. The effect of this extra length would be (if there were no counter influence simultaneously working) to lengthen the catenary from 300·0593ft. to 300·2213ft., and to increase the dip from 2·583ft. to 4·99ft., and to decrease the stress from 82·51lb. to 42·78lb. But while the expansion is thus proceeding to slack down the catenary, the resilience of the wire takes advantage of the decreasing stress to commensurately decrease the stretch; for of course the stretch cannot continue without the continuance of the stress which causes it. Thus the catenary resulting from this increase of length by expansion, and decrease of length by elasticity, instead of a dip of 4·99ft. and a stress of 42·78lb., has, in point of fact, a dip of 3·694ft. and a stress of 57·46lb.

There would be no material discrepancies between such calculations and facts if the calculator would remember that the coefficient of expansion and the modulus of elasticity are counter forces whose resultant is the catenary.

I state this not merely on theoretical grounds, but from close experimental acquaintance with the behaviour of steel wire catenaries of suspension bridges.—Yours, &c.,

Sunderland, October 8, 1887. FRANK CAWS.

THE LIGHTING OF WATERFORD.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We beg to hand you copies of two paragraphs which have appeared in *Invention* on September 24th and October 15th respectively, and which speak for themselves.—Yours, &c.,

LAING, WHARTON AND DOWN.

8 and 9, Holborn Viaduct, London, E.C.,
15th October, 1887.

"GAS *v.* OIL: THE OIL LAMP TRIUMPHANT.—We are glad to be able to announce that the street lighting of Waterford (Ireland) has been most successfully carried out by the Defries Safety Lamp and Oil Company, petroleum lamps having replaced all the gas lamps formerly used in the streets. This triumph of oil lighting has been achieved in the teeth of the most obstinate opposition by those interested in gas, who have not only smashed a number of the new lamps every night, but positively threw the lamplighter off his ladder one night. There can be no doubt that oil lighting, with the present improved lamps and at the reduced prices of petroleum, is proving a most formidable rival to gas when carried out by competent parties, such as the Defries Safety Lamp Company."

"GAS AND OIL.

"TO THE EDITOR OF 'INVENTION.'

"SIR: Referring to an article appearing in your issue of 24th ult., headed 'Gas and Oil: the Oil Lamp Triumphant,' I would beg leave to explain this matter in its proper light.

"The oil lamps do not deserve the praise they receive, neither are they a success.

"The City of Waterford is not lighted by them, but by the electric light, which lights all the main streets. The oil lamps only light the smaller and outskirting streets, and they are not as well lighted as they were by the gas lamps.

"The electric light is supplied from a plant fitted up by Messrs. Laing, Wharton and Down, on the Thomson-Houston system, which deserves the credit of superseding the gas, which it does very creditably, giving a very steady and beautiful light.—Yours respectfully, "A CITIZEN.

"Waterford, October 10th, 1887."

COMPANIES' MEETINGS & REPORTS.

Australasian Electric Light, Power, and Storage Company (Limited).

The shareholders in this Company held their fifth ordinary general meeting at Winchester House, 50, Old Broad-street, on the 17th inst., under the presidency of Mr. B. H. Van Tromp.

The CHAIRMAN reminded them that at the last meeting the arrangement with the Edison Company was confirmed, and it had been carried out. By that arrangement this Company obtained the absolute right to the Edison patents in Australasia, India, and the Cape of Good Hope, a stock of plant valued at between £4,000 and £5,000, and book debts to the amount of about £3,000, of which they had realised something under £2,000. Those assets they had paid for entirely in shares of their Company, which would receive no dividend until the 1 per cent. had been paid on the ordinary capital of the Company. The arrangement had placed them in the position of command of the whole market in Australasia, India, and the Cape of Good Hope; it left them, in fact, practically without a rival in those parts. With respect to the plant referred to, he must confess that its value was rather illusory. It was somewhat obsolete, but they believed they would be able to use most of it. They found that the agents, who had been connected for years with the Edison Company, were somewhat asleep, and they had to rouse them up. They had appointed a very efficient agent in India, with his centre of operations in Madras, and they hoped to hear some good news from that district. As to the Cape, nothing had been done there for some time past. The condition of things there had been almost as bad, if not worse, than in Australasia, where, as he had already said, they now held command of the position. The arrangement with the Edison Company had been a cause of much anxiety to the Directors, but it was satisfactory to believe that it must eventually redound to the benefit of the Company certainly, and he believed also to the Edison Company. The crucial question to be considered by the shareholders that day was, What had become of the capital of the Company, and what had been the result of the five years' operations carried on by the Company? And he believed he would be able to prove that the thing was not so bad as would at first sight appear. They must remember that the capital of the Company in the first instance was £120,000 only. There were certain vendors' and founders' shares, but those they need not take into consideration at all. As he had said, they had practically to deal with a sum of £120,000; and what had been done with it? In the very first year of the existence of the Company no less than £83,000 out of that amount absolutely disappeared as follows:—£45,000 was paid for the patents and £30,000 in shares; the Vogel mission cost them £5,000, and they paid £5,000 for the option of buying the Sellon-Volckmar accumulator. That amount disappeared without any result whatever beyond the fact that the Company became possessed of certain patents. The consequence was that the Company had been working with a very small sum of ready money. Even had the whole amount been called up at once they would have had only £40,000 to work with, and either in meal or malt they had that money still. They had been working for five years, and he would now show them how the debit balance was made up. £10,000 was attributable to the Vogel mission and the Sellon-Volckman accumulator. There had been an exceptional loss this year of £1,101, owing to the failure of one of their agents—Fletcher and Co. There were other exceptional items, such as the Randwick installation, interest, and discount, which increased the exceptional losses this year to £4,846, so that the actual loss did not exceed £22,000 for the five years. Then the cost of the Colonial establishment was £3,393, less profit on sales and goods, and the Theatre Royal installation, £2,186. The actual loss on the past year's trading to the end of 1886 was £1,207. The general charges in London, including discount and other charges, amounted to £1,270. Putting all these items together, they had only really lost on the five years' trading, as he had said, £22,000, and they had more than that as really fair assets subject to realisation, time being allowed for the Company to take advantage of any improvement caused by the

Digitized by Google

progress of the electric light. He put down their plant as being of the value of £15,000, but it ought to be worth very much more, judging by the amount realised by the sales taking place in Australia. Then they held shares in the Australian Electric Light Company to the amount of £18,000. Those shares they took as part payment of their patent rights in the City of Melbourne. The shares had been at par, but they had dropped down, and they were now said to be worth 7s. 6d. ; but the Company was now carrying on a lucrative business, and he hoped that the shares would soon reach par again. Another asset was the last call of 10s. upon which they had borrowed £5,000, leaving a balance for the Company from the call of £7,500. Those three items—stock £15,000, shares £18,000, and the call £7,500—made the £40,000. Their assets more than represented the loss they had made, and therefore they must still hope that the Company might eventually pull round and pay a dividend. He believed that opinion was shared by others in the room. With regard to their trading, the lighting of the Adelaide Exhibition had been a success, and had spread the celebrity of electric lighting throughout the colony. There would be a profit, he had no doubt, on that work, and they would be able to show that in their next balance-sheet. At the last meeting the Board were urged to see if some new arrangement could not be made whereby the standing charges of the Company could not be considerably reduced. That was a matter of great and deep interest to the Board, and they at once opened communications with Captain Rowan, their general manager in Australasia, pointing out to him most emphatically the necessity for reducing the charges. The Chairman detailed the course of the negotiations, pointing out the difficulty of dealing effectually with the matter, owing to the distance at which the correspondence had to be conducted, and said that it fortunately happened that Mr. Sanderson, one of the Directors, went out to Australia, and he kindly undertook to see Captain Rowan and look into the affairs of the Company generally. Mr. Sanderson took an immense deal of trouble, and the Board were very much indebted to him. He returned with certain proposals, and ultimately an agreement was made, but the matter was so delayed on certain small technicalities that the agreement was not made binding until August last. The consequence was that although the new arrangement was now in operation he feared that the accounts for the current year would not greatly benefit from the arrangement, but for the future it was certain to be very beneficial for them, inasmuch as the fixed charges could not exceed £682 for the 12 months. It would be very hard indeed if they could not get sufficient profit to pay that amount, and Captain Rowan would get nothing unless they did a volume of business which showed a larger income than the sum he had mentioned. In regard to the London expenses they had been reduced, and they would be further reduced. The services of Mr. Duncan, of the staff, and the office expenses, did not amount to many hundreds a year, and he could not imagine that the business could be carried on eventually, and to the interest of the Company, at a less expenditure than at present. With regard to the future, any gentleman in the room who was interested in electric lighting must be greatly delighted at the enormous progress that had been made throughout the world in the last year in regard to the light. In America over 30 millions sterling had been invested in the electric light industry, and nearly all of that amount was earning a dividend. As to Europe, there had been such a stir as to the immense importance of lighting large buildings with electricity that he believed within a year not a single theatre of any importance in any capital of Europe would be without it. He knew that in some countries they had made the existence of the theatres conditional on the use of the electric light. He had been much struck by reading the other day a lecture on electric lighting which was delivered by Prof. Forbes recently before the British Association. As they were aware, the progress of electric lighting in this country had been retarded in consequence of adverse legislation. Having quoted from Prof. Forbes's lecture, he said that what had been always urged against electricity was its enormous expense, but from what he had just read they would see that in the opinion of a man of eminence in the electrical world there was no reason why electric lighting should not be supplied to every town in the United Kingdom at the equivalent of 3s. per thousand cubic feet of gas. He (the Chairman) was speaking in the presence of a gentleman who was deeply interested in electricity, Mr. Ince, who was connected with the company that was supplying the electric light at the Grosvenor Gallery. That company was recently started with a capital of a million. They were putting up a magnificent station at Deptford with immense machinery. At that moment the company was supplying 20,000 lamps in London at a profit, and so eager was the desire for the light that as soon as they were ready, there was no doubt they would be able to light 40,000 lamps every night. Supposing they only realised a profit of 3d. a night, the shareholders would see how much that would represent in the course of the year. With the commanding position they now held, the arrangements they had made for reducing the charges, and their improved prospects owing to the progress of the electric light, he thought that there was a good future for their small Company. He did not for a moment believe that they would think of winding up the Company, but if they entertained such an idea they must remember that the very first thing the liquidator would do would be to call up the 10s. a share, and therefore as they knew that that was all they were liable for, the best thing they could do even in that view was to put off the evil day as long as possible, especially in view of their improved prospects. The day might come when the Directors would ask the shareholders to pay up the call, but if so they might depend upon it that it would be because the Directors believed that there was a good opportunity of investing the money advantageously. All the Board were agreed that if they could succeed in laying out this money in establishing a first-class lighting station in a large city, with a gradually but surely increasing business, that that was the best thing that they could do, and he thought that that would be the proper way in which they should lay out their money. They would only do so in a town where they had a perfect right to do so, and where they could not be interfered with, and where at a certain price they would realise a profit. He believed that it was the opinion of the whole world that the electric light was the light of the future, and he also firmly believed, that which he had believed ever since he saw the electric railway at the Crystal Palace eight or nine years ago, that it would be the future motive power. There were now no fewer than thirty electrical railways and tramways in full operation. There were thousands of ways in which electricity could be used in addition to electric lighting. All this was open to them in Australasia. There was no reason why, if it were desired to work a tramway there by electricity, the Company should not supply the machinery. In Genoa, Padua, Milan, Vienna, Paris, in all the principal towns of Europe, in St. Petersburg at that moment, every theatre was closed except a small one where French plays were given. Why was that? First, because the theatres must be altered to increase the facilities of ingress and egress, and it was a *sine quâ non* that the electric light must be supplied. He felt convinced that this progress of electricity which this state of things indicated must extend to Australia. It was true that the electric light had been progressing there for the last two years very slowly, but the Company would have done much more but for the drought and a desire on the part of the Australian people not to embark on any new undertakings. The Board would be most happy to answer any questions, for he could assure them that there was nothing whatever to conceal, and that there would be no secret from the shareholders. He concluded by moving the adoption of the report and accounts.

Mr. J. J. CATER seconded the motion.

Mr. GUESDON thought it would be more advantageous for the Company to call up the 10s. a share and pay off the £5,000 which had been borrowed against it, seeing that they were paying interest on the amount.

Mr. INCE said he fully acquiesced in the view of the Chairman in thinking that the future of the Company was not without hope ; in fact, he himself would venture to go further, and say that if the shareholders would pull with the Board, as he trusted they would, the future of the Company would yet be a success. There was no doubt that when they started the Company, in which he was a very large shareholder, it was imagined that a great deal more was known about electrical science than was known. They were practically at that time not in a position to deal with the lighting from large central stations ; they were not in a position to distribute the electrical current at a distance through mains of such size as to be sufficiently economical to leave a profit. That difficulty had now disappeared, and it was now possible to transmit electricity economically through mains of such size that they could light not only the whole of London from one centre, but a city much larger than London was, or was ever likely to be. As to the remark of the last speaker, he thought that in the present position of affairs the Board had acted wisely in borrowing a certain sum of money at interest rather than call up the balance due from the shareholders. He thought that this matter should be left *in statu quo*. They had not now to put before the shareholders any hypothetical case, or to state that they had certain patents, and that they "believed" certain things could be done. Central stations had been started in England and America, and in both countries they were a great success. They were yielding profits with which the shareholders were satisfied on both sides. In the company with which he was associated he certainly anticipated a dividend such as would thoroughly satisfy all the investors in it. He could see that the time would come when the Board would have to ask the shareholders to meet them by subscribing a certain further amount of capital than that which they already possessed. He ventured from his own knowledge of the subject to be prophetic, and to say what sum they ought to ask for in the first instance. Taking the capital of the Company roughly as representing £200,000, he thought that in order to start a central station, which would leave such a return as would thoroughly satisfy the shareholders, the Directors ought to look forward to increase their capital by 10 per cent. ; and when they asked him to subscribe his proportion he would come forward readily and do it, and he trusted that the other shareholders would follow suit. He believed that the capital so raised could be invested in Australia to yield a profit of 20 per cent., having regard to the price of gas, and once they started such a station they would have no difficulty in establishing others from which the profits would be equally great. He firmly believed that if they would help the Directors the whole of the present capital, which was now worth practically nothing, would become valuable. In the case of the undertaking with which he was connected they were selling the current at a price equal to 4s. per thousand cubic feet of gas, and at that price it was being taken up very rapidly. He could see that as the number of lights taken from the central stations increased to a great extent it would be quite possible to reduce the price to 3s. He ventured to be prophetic, and to say that the electric light even at the present price was going to stamp out gas as an illuminant, and more than that, he believed that the time would come when the electric light would snuff out gas, not only by reason of its superiority, but because it was cheaper than any gas now supplied in the City of London.

Mr. VERITY said that being an Edison shareholder he was not conversant with what had gone on in the Australasian Company generally. When the arrangement between the Company and the Edison Company was made he said he thought it was a bad bargain for the latter, but now that they were members of the Australasian Company, seeing that they held the whole of the patents for Australasia, India, and the Cape, he thought that their position was a good one. The Directors had great difficulties to contend with, but the share-

Digitized by Google

holders really must ask them to do their utmost to prevent the lamentable loss every year which they had hitherto sustained. He dissented from the proposal that they should establish central stations, because they did not hold the patents that were requisite. He thought that the Company should simply sell its dynamos and lamps—to do, in fact, what the Edison and Swan Company did. That company were giving up their installations, and were selling their lamps and dynamos.

A SHAREHOLDER asked whether some of the shares were not fully paid up already.

The CHAIRMAN, in reply, said that all the shares that were issued to the Edison Company as a consideration for the purchase of their assets were fully paid up, and so also were the shares which were issued to the vendors of the Brush patents to the Company. As regarded the capital of £120,000, however, all of those shares had a liability of 10s. each.

Mr. M'MILLAN said that he thought that the course before the shareholders was perfectly clear, and that was to support the Directors. He could not agree with the observation that had been made that it would be politic for the Directors to call up the 10s., for the very fact of there being 10s. to call up gave the Directors a better opportunity of exercising a certain amount of credit. He was perfectly satisfied to accept the statement of the Chairman and patiently to await the issue of events. Possibly the undertaking might turn out a great success, but the worst that could happen would be the loss of 10s. a share.

Mr. SANDERSON, at the request of the Chairman, then addressed the meeting, especially in regard to the arrangements which he had made with Captain Rowan, and the result, as already intimated by the Chairman. He expressed his opinion that in Captain Rowan the Company had a most able representative. With respect to their investment of £18,000 in the Australian Electric Company of Melbourne he saw a great deal of the members of that Board when he was in Melbourne, and it was a Company which had every element of success in it. They were lighting the Princess's Theatre and the Theatre Royal, and he was sure that all their customers were exceedingly well satisfied. He believed that a lighting station at Sydney would pay very well, and that if they had a station there when Australia was successful and had plenty of money it would be a great success. He had on his return from Australia visited India also, and he thought they had very good prospects in India also, and altogether, in view of the great strides which had been and were being made by electric lighting in England, he believed that the progress would extend to India and Australia, and that a dividend would come to them soon.

The CHAIRMAN, in reply, at the close of the discussion, said that the principal profit they had made in Australasia had been from the dynamos and other plant they had sent out, not from the lamp patents. He had been very glad to see Mr. Verity among them, for that gentleman had turned his attention to and believed strongly in the electric light as the light of the future. If electricity had preceded gas, the electric light would have been in every town long before now, but it had had the enormous monopoly of gas to fight against. That, however, was breaking down. In the City of Christiania the Corporation were the owners of the gas works, and they had determined to abandon gas except for cooking and heating purposes, and to supply the the whole of the city with the electric light. He believed that the same would be done in England yet; in fact, it had been done at Leamington, which had decided to abandon gas and to adopt electricity for the whole of the town. If they could see their way of profitably increasing the capital by 10 per cent. they would be prepared to do so at the proper time. He regretted that Major Flood Page was absent, owing to an accident which had confined him to his room. He was a most able Director of the Company. He then put the report, and it was unanimously adopted.

On the motion of Mr. SANDERSON, seconded by Mr. INCE, Mr. Latimer Clark, C.E., and Mr. Philip Falk were unanimously re-elected Directors of the Company; and the auditors (Messrs. Deloitte, Dever and Co.) were also reappointed.

Mr. M'MILLAN then proposed, and Mr. INCE seconded, a vote of thanks to the Chairman and Directors, which was unanimously agreed to.

The CHAIRMAN acknowledged the vote, and said that the Directors would do their utmost to promote the welfare of the Company.

The meeting then terminated.

The Water Primary Battery Company.

We take the following from the *Financial News* of the 14th inst.:—

The ordinary general meeting of the Water Primary Battery Company (Limited) was held on Tuesday, at 265, Gresham House, Broad-street, E.C., Colonel G. B. Malleson, C.S.I., presiding.

The notice convening the meeting having been read by Mr. W. H. Smith,

The CHAIRMAN said: Gentlemen, I have very great pleasure in introducing to you the inventor of the water battery, Mr. D'Humy, who is a very old friend of mine, for I have known him many years, and know he is a gentleman who possesses one of the most inventive minds in Europe (applause). No single invention of his have I seen which is not capable of practical application (applause). With regard to this Water Primary Battery I have taken various engineers of my acquaintance to the office with the express idea on my part that they should be able to pick a hole in it; but not one of them has succeeded in that (hear, hear). Gentlemen, with these few remarks I shall call on Mr. D'Humy to address you on the points which he may consider necessary.

Mr. P. R. DE FAUCHEUX D'HUMY said he would do his best to give as clear an explanation as possible. Last year, on December 23rd, he formed a company with a capital of £100,000 in fully paid-up shares, £20,000 being given to him as the vendor, as well as the shares in payment for all plant, machinery, and stock, and also for the English, French, American, Indian, Belgian, Austrian and Italian patents of the Water Primary Battery. He started the company without calling any capital from the public, and to show his confidence in the invention he had paid all the expenses up to now to bring the Company to its present success, and he had acted as an ordinary traveller, instead of the Managing Director of the Company, in trying to obtain orders. Since December 23rd he had manufactured a big battery, to be demonstrated at 26, Gray's Inn-road, as a specimen of a central station battery for lighting a number of houses. For ten months this battery had been going day and night, and he had invited the public and all the scientific world of Europe to visit the place and inspect it. For ten months it had been working with no need for repair. The invention had made some sensation in Europe. Municipalities and Governments had sent their engineers and confidential men to report on it, and it had given satisfaction to everybody (applause). It had been proved that the battery could be worked as well as the dynamo, and that a large field was open to it for supplying electric light (applause). He had succeeded in obtaining very important concessions for it in various big cities, and on Sept. 16th last he had obtained a concession for lighting Madrid by electricity—and about 200,000 lamps would be required within the next four years—and had given the contract for the execution of the said work to the Water Primary Battery Company (Limited) (hear, hear). Official document and decree were now before the Chairman. He had sold the patent for France for £100,000, which was to be paid by a syndicate, according to French law—that was to say, a fourth of the amount would be paid almost immediately. Since he sold the French patent he had received a letter from France telling him that the syndicate were obtaining orders very rapidly (applause). This Company would be the contractors for the French company, supplying all the water battery appliances, and the transaction would be very profitable. This Company, he pointed out, had started with no capital, and their manager had never received a salary, but working as an ordinary clerk he had succeeded in making a very good report, and was able to say that next year on the original capital of £100,000, the shareholders would receive a dividend of about 100 per cent (cheers). For years he had carried on a fight with engineers and scientific men of Europe. Nobody would believe that from water the power to light by electricity could be obtained; but he had proved that with water and a metal that did not destroy—that was to say, with common iron plunged in water—he could obtain a result that was reputed in the scientific world to be impossible (cheers). Every week for ten months he had had 600 or 700 people at his office to inspect the invention, and he had shown to the engineer how to distribute the electric current with no mechanical difficulty, and proved to the uninitiated on the subject how he could manufacture his own electricity at his home. Lately he had made another invention, which would, he was sure, be very popular in all Europe, and he had been offered £30,000 for the patent in France. It was a very small battery, and he had received applications for it in reference to one, two, three, four, and ten lamp-power for lighting very small houses and small workshops. He had given a long course of study to the subject, and to-day the invention was complete. It consisted of a little battery which was automatic, and capable of working for many years. The problem had been solved with the water battery, and the two inventions had become very popular in the world. He had established the water battery in the confidence of contractors in the north of England, and had succeeded in getting a staff ready to manufacture the water battery and the small battery on a large scale. The company possessed in the North of England a very large amount of business, and had made a contract with an important firm for the manufacture of both batteries, viz, with Messrs. J. Butler and Co., of Stanning'ey, near Leeds, who had so much confidence in the future of the invention that they had not hesitated to take shares and debentures as the consideration, so that for the present this Company was in a position to form several large centres without expending a single shilling (applause). Propositions had also been made by another important contractor who was desirous of joining the contractors in the north and working with them, and had offered a large sum of money to enter into the concern. This, he thought, was all he had to explain.

Mr. W. H. SMITH asked Mr. D'Humy to give some further explanation as to the concession at Madrid.

Mr. D'HUMY said that concession did not belong to this Company, but to him personally; but he had transferred the work, under contract, to the Company, and they would make a large profit out of it—£25,000 or £30,000 (cheers). He was also negotiating for the sale of the patent at Belgium, Austria, America, and other countries, and these sales would also bring some important profits to this Company (cheers).

The CHAIRMAN said it had occurred to him while Mr. D'Humy had been speaking that the success of every enterprise depended on the fact that the basis of it was sound and valid. He did not know whether all the gentlemen present had seen the water battery at work, as he had, but if anyone had the slightest doubt of the validity and value of the machine, and its ability to effect what Mr. D'Humy said it could, let him put any questions to that gentleman, and he would, no doubt, answer to his own satisfaction and to the satisfaction of them all.

Colonel INNES said he did not profess to know anything about electricity, but some months ago he made an examination of the invention, and was very pleased with everything he saw. But in making inquiries in reference to the lighting of the Chesham Gallery, Old Bond-street, he went to three or four firms, and in discussing this Company's invention one man, a thorough electrician, declared the plates would never last. He should like some explanation on this point.

Mr. D'HUMY said in the water battery there were two kinds of plates—one iron, the other carbon. The objection referred to the carbon plate. Undoubtedly, if there were any silica in the carbon plate it would perish;

Digitized by Google

but in his invention there was no silica, but pure carbon, and therefore it was indestructible (hear, hear).

Mr. DAWSON PHILPOT said when he had denied that there was any decomposition of metal, he was met with the reply that in that case there could be no light.

Mr. D'HUMY said instead of a decomposition of metal there was a decomposition of nitric acid, which was enclosed in a reservoir in the machine. A pound of nitric acid cost 2d., and would produce light for 15 lamps of 10 candle-power each (hear, hear).

Mr. OXLEY raised a question as to the business now in hand, in reply to which,

Mr. W. L. MAITLAND stated that he had the business of the Company in hand only a little over a week, and in that time he had obtained for Mr. D'Humy close on £15,000 worth of orders (cheers). His fear was that they would not be able to supply all the customers he could bring them.

A SHAREHOLDER: The orders are chiefly to do with theatres, I think?

Mr. MAITLAND: Yes, and other large buildings. Two large contracts have been closed, and two will be closed within a week, and two others also within a week, for large stores.

The CHAIRMAN: That is very satisfactory; but it will be still more satisfactory if Mr. D'Humy tells us he will be able to supply all orders rapidly.

Mr. D'HUMY: Oh, yes; we have the contractor in this room—Mr. Butler—who has more than 1,000 men at work in his factory, and will be able to manufacture very rapidly so as to supply the demand.

The CHAIRMAN said it had been suggested to him that Mr. D'Humy should explain to the meeting the working of the battery; but his answer to that was that it would be far better if gentlemen who had not seen the works should go and see them. He was sure Mr. D'Humy would explain on the spot the mode of working and the principle on which the work was carried out (hear, hear).

Mr. D'HUMY: With the greatest pleasure. Replying to a question as to the price of the light supplied by the Company, Mr. D'Humy said the battery would supply the light at exactly the price of gas. If the Company only supplied the light it would leave them a small profit (cheers), but it would be quite the exception that they supplied the light without the battery. For a very small installation the cost would be 10 or 15 per cent. above the price of gas.

Mr. W. H. SMITH moved a vote of thanks to the Chairman for his kindness in attending the meeting. He knew Colonel Malleson's engagements were such that it was very difficult to get hold of him; but they also knew that he was always ready to help on any scientific object for the benefit of the world in general (cheers).

The CHAIRMAN said he thought their thanks were due rather to Mr. D'Humy for the explanation he had given (cheers). He thought they must have been struck with wonder and admiration at the ease with which the light could be produced under the Company's system, and which when produced by the ordinary way of dynamo, caused great disturbance in private houses, and a great deal of unpleasant noise in larger premises. He was sure that those who went to see the battery would go away with wonder at what science could do, especially in the hands of such a skilful man as his friend Mr. D'Humy.

The proceedings then terminated.

Eastern Extension, Australasia, and China Telegraph Company (Limited).

Report and accounts of the Directors for the half year ended 30th June, 1887, to be submitted to the twenty-eighth ordinary general meeting, to be held at Winchester House, 50, Old Broad-street, E.C., on Wednesday, the 26th inst., at 2 o'clock:—

The usual statements of account for the half year ended 30th June last show that the gross receipts, inclusive of Government subsidies, have amounted during that period to £219 201. 4s. 8d., against £224,843. 0s. 1d. for the corresponding half year of 1886. The working and other expenses, including £26,408. 9s. 7d. for cost of repairs to cables and expenses of ships, absorb £76,241. 3s 6d., against £81,775. 7s. 1d. for the corresponding half year of 1886, leaving a balance of £142,960. 1s. 2d. From this is deducted £3,702. 16s. 5d. for income-tax, and £41,595 for interest on debentures and contributions to sinking funds, leaving £97,662. 4s. 9d. as the net profit for the half year, against £97,480. 5s. 8d. for the corresponding period of 1886. One quarterly interim dividend of 1¼ per cent, amounting to £31,250, has been paid during the half year, and another of like amount was distributed on the 15th inst., leaving £35,162. 4s. 9d. to be carried forward. In accordance with the provisions of the trust deed, dated 10th May, 1879, 264 Five per Cent. Australian Government Subsidy Debentures were drawn on the 29th April last, for the payment at par on the 1st July. The numbers of the drawn debentures will be found on page 12. The Company's maintenance ships have been kept employed on various cable repairs during the half year under review, but no interruptions of a serious nature have occurred. The Company's hulk "Southern Ocean," stationed at Singapore during the last eight years, having been reported to be unsafe as a floating cable establishment in consequence of ravages of white ants, the vessel has been dismantled, and the machinery and cable tanks removed therefrom to the Company's new shore cable establishment at Singapore. The hulk has since been sold by public auction. The subject of reduced tariffs between Europe and the Australasian Colonies was discussed at the Colonial Conference recently held in London, and the proposals submitted by the Company based upon a Colonial guarantee or subsidy are now before the Colonial Governments. The South Australian Government land line between Port Darwin and Adelaide has, as usual, been satisfactorily maintained during the half year under review.

CITY NOTES, &c.

ANGLO-AMERICAN TELEGRAPH COMPANY (LIMITED).—At a meeting of the Board of Directors of this company held on the 14th inst., it was resolved "to declare an interim dividend for the quarter ending 30th September, 1887, of 7s. 6d. per cent. on the ordinary stock, and 15s. per cent. on the preferred stock, less income-tax, payable on the 1st November to the stockholders registered on the books of the company on the 7th October, 1887."

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 17th October amounted to £3,566.

CONSOLIDATED TELEPHONE CONSTRUCTION AND MAINTENANCE COMPANY.—The directors have resolved to pay an interim dividend at the rate of 5 per cent. per annum in respect of the current year.

EASTERN TELEGRAPH COMPANY (LIMITED).—This Company announces the payment, by interest warrants, on the 1st November next, of interest for the half-year ending the 31st October, on their Four per Cent. Mortgage Debenture Stock.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 14th October, 1887, were £2,752, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half-month ended 15th October are £2,629, as compared with £1,863 in the corresponding period of 1886.

PARTNERSHIP.—Mr. J. F. La Trobe-Bateman informs us that he has taken into partnership with him his son, Mr. Lee La Trobe-Bateman, and also the Hon. Richard Clerc Parsons. Mr. Parsons' name is well known to electrical engineers in connection with the high-speed turbine steam engine.

NOTES.

DISTURBED IRELAND.—Again, on Sunday night last, the telegraph wires were cut, this time between Kilrush and Ennis.

GOLD MEDAL AWARD.—Messrs. Ransomes, Sims and Jefferies have received the highest award—a gold medal—for their exhibits at the Charkoff Exhibition.

PALENCIA (SPAIN).—The municipality of Palencia announces that it is proposed to receive tenders for lighting the streets of that town by electricity. The present cost of gas lighting is a little over £500 per annum.

TURKEY AND GREECE.—The Post Office announce that telegrams are now transmitted by the route of the Eastern Telegraph Company to Turkey at a charge of 10d. per word, and to Greece and the Greek Islands at 7½d. per word.

BOOKS RECEIVED.—"On a Surf-Bound Coast; or, Cable Laying in the African Tropics," by Archer P. Crouch, B.A., Oxon. London: Sampson Low.—Also from Messrs. Longmans, Green and Co. a copy of "A Handbook for Steam Users," by Mr. M. Powis Bale.

THE "EMPIRE" MUSIC HALL.—The electric lighting contract for this gigantic building has been placed in the hands of Mr. Harry South, of 10, John-street, Adelphi, W.C. Engines and boilers of over 100 horse-power are to be erected, and some 1,200 incandescent lamps will be run.

THE FRENCH INSURANCE OFFICES.—In consequence of the catastrophe at the Opéra Comique, and notwithstanding the fact that electric light is now compulsory in the Parisian theatres, the French Fire Insurance Offices have given notice of an increase in the tariff for the insurance of theatres.

THE GÜLCHER COMPANY.—We hear that at the present time this company is busy in all departments, having received several important contracts, amongst others, for 64 arc lamps for the Olympia Hall, the lighting of the new markets at North Shields, and three mills in Yorkshire, besides several small contracts.

AN INQUIRY.—The New York *Engineering and Mining Journal* mentions that it has recently had an inquiry, coming from a district where fuel is scarce and water-power cheap and plentiful, as to whether it would be possible to employ the latter power to obtain heat for the purpose of roasting ore by means of the electric current.

THE ATLANTIC CABLES.—A number of rumours relating to a further amalgamation of the several Atlantic Cable Companies, and a possible increase of the tariff, have been going the round of the financial and daily press for some time past. We have reason to believe that none of these statements are published on authority, and that they are for the most part purely conjectural.

THE LIGHTING OF THE CITY.—The Paving Committee of the St. Saviour's Board of Works has recommended the Board to accede to the application of the Anglo-American Electric Light Corporation for permission to carry their mains under the footway of Blackfriars-road, on condition that the company should supply light in that district on the same terms as elsewhere.

TRENTE (TYROL).—The Municipality of the town of Trente, in the Tyrol, has under consideration a scheme for lighting the streets by electricity, motive power being obtained from the falls at Fersina, a distance of 2½ kilometres. These falls are about 25ft. in height, and the current is sufficient to yield from 400 to 800 horse-power according to the season. The estimated cost of the installation is about £8,500.

ELECTRIC SAFETY LAMPS IN MINES.—From a letter addressed to *The Times* on Friday last by the secretary of the Edison and Swan Company, we learn that the trials of their lamps in the Risca pits, commenced last April, have proved so successful that Messrs. Watts, Ward and Co. have ordered 2,400 electric safety lamps to be manufactured, with a view of superseding all the existing lamps in their extensive South Wales collieries.

THE FRENCH TELEGRAPHS.—M. Coulon, the Director-General of Posts and Telegraphs in France, has summoned a commission of the higher officers of the establishment to consider amongst other matters the following important questions:—The employment of the system called steno-telegraph, by which messages are transmitted by stenographic signs; the introduction of multiplex telegraphy; the use of the electric light in telegraph offices.

THE PRICE OF GAS.—We notice with satisfaction the announcement that the price of gas in that part of the metropolis situated north of the Thames will be reduced on the 1st January next from 3s. per thousand to 2s. 9d. per thousand. While not in any way hindering the progress of electric illumination, this reduction will diminish the cost of working gas engines, by means of which a considerable amount of electric lighting is at present maintained.

A CHANCE FOR THE YOUTHFUL GENIUS.—The *Société Industrielle d'Amiens* announces that it is prepared to award an indeterminate number of gold medals (value 200 francs) for as many essays dealing with any department of theoretical or applied electricity as may appear to possess sufficient merit. Manuscripts, which must presumably be written in French, should reach the President of the Society at No. 29, Rue de Noyen, Amiens, on or before 30th April, 1888.

NEW YORK ELECTRICAL CLUB.—At the monthly dinner of the New York Electric Club, announced to be held on Thursday, October 20th, the topic of the evening, to be introduced by Prof. Leonard Waldo, of Yale College, was the question, "What is an Electrician?" We learn with satisfaction that Prof. Waldo "proposed to look at the question from the standpoint of establishing something of the professional *esprit de corps* of the legal or medical profession."

TAMPERING WITH TELEGRAMS.—At the Central Criminal Court on Monday, Harry Wilkes, telegraph clerk at the General Post Office, having pleaded guilty to the charge of altering certain racing telegrams received by him from Sandown, was sentenced to one month's imprisonment. The lightness of the punishment is explained by the prisoner's youth, and the fact that he had been tempted by betting men much older than himself, and apparently not to his own profit.

CUTTING GLASS TUBES.—E. Beckmann in the *Zeitschrift für Analyt. Chemie* gives a neat method for dividing glass tubes which are too large or too thick to break with a mere file nick. He scratches round with a file at the line where the division is required, then wraps around the tube on each side of the mark a strip of wet filter paper and applies a Bunsen burner, or, better, a blow-pipe flame. The method is equally good for the thickest glass tubes and the thinnest beakers. The space between the strips of filter paper should not be more than one to two millimetres.

INTERNATIONAL TELEPHONE SERVICE.—Some little while ago we recorded the fact that arrangements were being made

Digitized by Google

for the establishing a system of international telephonic communication between neighbouring towns in Western Germany, Belgium, Eastern France, and Switzerland. Mulhouse and Bâle have already been connected, and financially the experiment gave every promise of success. Suddenly, however, the German Government has announced its intention to withdraw entirely from the scheme, and the lines already erected will be abandoned. Political reasons are supposed to have dictated this measure.

THE HAMMOND ELECTRIC LIGHT AND POWER SUPPLY COMPANY.—We publish in another column a report of the meeting yesterday of this company. From the statement made by Mr. Wm. Theobald (the liquidator) it will be seen that great difficulties had to be contended against, but considerable judgment was brought to bear upon them, and with a result which, under the circumstances, cannot be regarded as other than satisfactory. At one time it was feared that the creditors might not be paid in full, but their claims have all been discharged, and there is to be a return to the shareholders of 3s. a share.

A GEISSLER TUBE PHENOMENON.—M. Kündt, whose researches on electro-optical phenomena are familiar to the student of "advanced" physics, has recently examined the metallic layer which is frequently found in a Geissler tube from the material of the negative electrode, and he finds that it possesses the property of double refraction. Viewed by transmitted light these layers, which are of excessive tenuity, have the following colours :—

With gold electrodes	.....	Green, slightly bluish.
„ silver „	.....	Blue, slightly violet.
„ copper „	.....	Dirty green.
„ platinum „	.....	Greyish blue.
„ iron „	.....	Grey.
„ nickel „	.....	Grey.

The least trace of oxygen in the tube produces a deposit of the oxide, even with gold, silver, or platinum, although the electrode itself remains un oxidised. By reflected light under oblique incidence Newton's rings are seen. Further information on the subject may be found in *Wiedemann's Annalen*, Vol. XXIX., p. 353.

DISTRIBUTION OF TIME IN AMERICA.—Time is transmitted every day from Washington to the chief ports of the Atlantic seaboard. From three minutes before noon till the stroke of noon the time is sent, second by second, with the exception of those which mark each half-minute and the five seconds which precede the exact minute. The Western Union and Baltimore and Ohio Telegraph Companies (recently united) give up the use of their wires free of indemnity for this purpose. Wherever the time is sent, an electro-magnet gives the signal sent from the distributing saloon in the Washington Observatory. At noon precisely the electric current drops time-balls at New Orleans, Savannah, Washington, Philadelphia, New York, Newport, and Woods Holl, in Massachusetts. Boston is served directly by the Cambridge Observatory. The Pacific ports are supplied from an observatory at Mare Island, near San Francisco. Private and institutional clocks are also corrected by the time currents. Some establishments, such as the fire stations, the signal office, and the coast survey, have direct telegraph lines by which they can get the hour at any time. There are many manufacturers, clockmakers, and others who subscribe for it.

THE INSULATION OF ELECTRIC LIGHT CONDUCTORS.—Writing on this subject in *L'Electricien*, M. Hospitalier makes the following very truthful observations :—"Theoretically speaking nothing is more easy than to define the insulation resistance of any system of electric conductors whatever ; but nothing, on the contrary, is more difficult, in practice, than to determine the insulation of such a conductor under conditions which correspond exactly to those of its employment. We lack a method simple and practical which shall permit the comparison of different samples and give a just and fair appreciation of their respective values. Some are content to indicate the insulation required in a manner purely sentimental, without being concerned with any of the conditions of usage, which, as we know, have so great an influence upon the value of the insulation resistance ; others prefer to specify the nature of the insulation, and of the mechanical protection ; others, again, do not even take as much trouble as this. . . . . The legend of the Tower of Babel gives only a vague idea of the confusion which exists upon this question, which yet is one of supreme importance to the electrical industries." Some day, perhaps, we shall have in this country a corporate body capable and willing to undertake the task of dealing with the problem here indicated.

ELECTRIC LIGHT FOR WIMBLEDON.—At a meeting of the Wimbledon Local Board on the 19th inst. a proposal to take steps to obtain a provisional order for electric lighting was unanimously adopted. A wealthy suburb such as Wimbledon undeniably affords a promising field for domestic lighting, and if proper advice is obtained we know no reason why the Local Board should not achieve a decided success. We hope, however, that they will not permit themselves to fall a prey to any specious offers to carry out the scheme "on the cheap." The proper course to pursue in a scheme of this magnitude is undoubtedly to obtain specifications and estimates from some consulting electrical engineer of acknowledged status, who should also undertake the responsibility of seeing the work properly carried out from beginning to end. The only other admissible alternative is to ask for specifications and estimates from a number of first-class firms. Wimbledon is fortunate in numbering amongst its inhabitants more than one electrician of the foremost rank, so that the Local Board need not go far to seek for competent advice. Mr. Chatterton, who proposed the motion, made some sensible observations as to the probable cost to the users. He pointed out that electric lighting was admittedly a luxury, but where they had a sufficient number of wealthy residents he had no doubt that people would be as willing to pay for this luxury as for others.

CENTRAL STATION LIGHTING AT LIVERPOOL.—A Liverpool correspondent writes :—"The Committee of the Liverpool Corporation have recently been in communication with the Liverpool Electric Supply Company with regard to an application for a license which the above company are making to the Board of Trade. The terms of the draft license so prepared were approved at a general meeting of the council on Wednesday. The terms of the license provided for the continuous supply of electricity in the chief business and residential portions of Liverpool, the supply to be measured by meter, and to be charged on a sliding scale, varying from 1s. per unit for consumers who do not use the light for more than 400 hours a year to a price approaching fourpence per unit when lights are used continuously all the year round. A consumer using his lamps 1,200 hours per annum would pay at the average rate of 8d. per unit. A special clause is inserted in the license by which the theatres and other public buildings are entitled to be supplied at a reduction of 33 per cent. from the above prices. The Liverpool Electric Supply Company have had a central station

Digitized by Google

operation for the last four years, and have therefore some experience as to public supply. They have recently finished a second central supply station, and a third and larger station is now in course of construction. Messrs. Holmes and Vaudrey are the engineers of the company."

AN EXAMPLE TO BE FOLLOWED.—The Vienna Industrial Museum has recently started a testing establishment which should prove of great value to electrical trade in Austria. Its provisional table of charges is as follows:—

Dynamos, according to size and tests required	£1	10	0	to	£5	0	0
Glow lamps, efficiency on photometer	1	0	0	to	5	0	0
Glow lamps, candle-power only	1	0	0			—	
Arc lamps, efficiency	1	10	0	to	2	0	0
Arc lamps, candle-power only	1	10	0			—	
Measuring instruments	0	10	0	to	2	0	0
Arc lamp carbons	1	0	0			—	
Specific resistance tests	1	0	0			—	
Temperature coefficient tests	0	12	0			—	
General photometric investigations on various sources of light	0	6	0	to	2	0	0

If the results are to be published a further payment is to be made to the funds of the institute. Such an establishment ought to be a success, and no doubt the provisional list will be much extended before long. We do not often introduce political cries into these columns, but we do feel moved by this to inquire, "Why should London wait?" Surely we ought by this time to have a standard laboratory of our own, where authoritative and impartial tests would be carried out by competent men. The question is one which will no doubt receive the early attention of the Association of Electrical Engineers whenever that coming organisation blossoms into actual life.

ELECTRIC STREET RAILWAYS IN AMERICA AND ELSEWHERE. A New York paper gives a list of seventeen street lines now operated by electricity in the States. Of these no less than fifteen employ overhead conductors, and the remaining two are conduit systems. When we consider that the overhead system is absolutely out of the question in this country, and that as regards the public streets the conduit systems have yet to demonstrate their "permissivity," the difference between the rate of progress here and over the water is not so surprising. Battery systems do not come immediately into the same category, because with them it is no longer a question as to practicability but as to economy, and this must take time to decide. Meanwhile we learn with regret that the only battery system (except Elieson's) at present in regular operation—namely, Julien's—is not doing at all well at Brussels. The charging station seems, in the first place, to have been badly designed and ill equipped, and difficulties of a quite unnecessary character have arisen there. But a still more fatal mistake was made in the assumption that anybody's dynamo would do for a motor. That fallacy is now, we take it, on its last legs. M. Julien was lately in this country negotiating with a prominent firm who supply electric motors, and we have reason to believe that the Brussels line will shortly be re-stocked with an efficient plant. Returning to America, the same paper gives a further list of eighteen lines in course of construction or under contract, and no less than fifty-five new roads projected, the whole of which are to be worked electrically.

COAST DEFENCE BY ELECTRICITY.—Although the recent operations in the attack and defence of Langton Harbour were conducted under unusually stringent conditions as to secrecy, it is stated, apparently on good authority, that both the War Office and the Admiralty have been strongly impressed with the great value of the electric search light in such operations. Electricity lends its powerful aid both in attack and defence, and equally above and below the water level; and now that the authorities seem at last to have taken up the question of coast defences in something like an earnest spirit, there can be little doubt that a good many orders for arc light equipments will be forthcoming within the next twelve months. Dynamos and engines and quick-firing guns are less expensive to equip and to maintain than permanent fortifications; they are a good deal more mobile, and more easily procured than heavy artillery, and while it is of course essential that our naval yards and harbours should continue to be protected in the old-fashioned way, yet we may doubtless look forward to the period when without exception all points of our coast line where an invader might attempt to gain a foothold shall be at least within easy hail of the modern system of electrical defence. For this, however, skilled manipulation and familiarity with electrical apparatus is essential. In the Volunteer Coast Defence Brigade which is contemplated we have no doubt that many of our readers will bear an honourable part. We are not aware that it is at present within our power to render any direct assistance to the movement in these columns, but should occasion arise it is scarcely necessary to add that we shall be eager to avail ourselves of the opportunity.

AN IMPORTANT ELECTRIC LIGHTING COMBINATION.—Some months since the Thomson-Houston Electric Company commenced the installation of a number of incandescent electric lighting plants in various American towns, in which the distribution was effected by means of transformers. Upon this legal proceedings were instituted by the Westinghouse Electric Company, alleging infringement by the former company of the Gaulard-Gibbs patent, which is owned and controlled by the Westinghouse Company. It is now authoritatively announced that the suit has been withdrawn, and that an amicable arrangement has been entered into between the two companies, by which they will hereafter work in harmony and in close business relations. It is learned that by the terms of the agreement, the Thomson-Houston Company acknowledge the validity of the Gaulard-Gibbs patents relating to electrical distribution by alternating currents, and will hereafter work under a license from the Westinghouse Company. The Thomson-Houston Company acquire the right to install the Westinghouse system in the six New England States, and also in connection with the arc lighting plants which it has established in the principal towns and cities throughout the United States, some 200 or more in number, most of which are operated by local companies; while, on the other hand, the Westinghouse Company will install the Thomson-Houston arc system wherever a plant of that kind may be needed in connection with the Westinghouse stations. The joint product of the extensive manufacturing establishments of the Westinghouse Electric Company at Pittsburg and the Thomson-Houston Company at Lynn will amount to several thousand lamps per day, together with the necessary dynamos and transformers, and the present indications are that the facilities of both factories will be taxed to the utmost to supply the immediate future demands for the extension of electric lighting in the States.

INSTALLATION AT LLOYDS, BARNETTS AND BOSANQUETS BANK.—The new premises of this bank, at 72, Lombard-street, have been supplied with an installation of 270 incandescent lamps by Latimer Clark, Muirhead and Co., of Westminster. Motive power is obtained from a Crossley "Otto" gas engine of 14 horse-power nominal (or about 33 indicated horse-power),

Digitized by Google

fixed upon a stone bed underneath which is placed 4in. of hair felt. Air spaces are left also all round, and no vibration is felt in adjoining premises. The exhaust is taken a considerable distance horizontally in iron pipes, and then rises vertically in an air shaft to summit of building about 60ft. high. Cooling water is drawn from water main, and hot water runs to waste. Provision is made for measuring the quantity of water used. On a recent occasion about 29 per cent. of the total heat of combustion of gas used was found in the cooling water. This engine drives a 14·4-unit Westminster dynamo at 1,200 revolutions. The machine is shunt wound, horizontal type, by Latimer Clark, Muirhead and Co., and is fitted with worm wheel adjustment for brushes, and with automatic arrangement for switching on charging current when the electromotive force at terminals attains the proper amount. A battery of 104 E.P.S. accumulators of the 31 L type is employed; these cells were manufactured by Elwell-Parker and Co, to a specification by Drake and Gorham. A Blackman air propeller, driven by a belt from the engine shaft, keeps the room cool, and carries off the fumes from the cells. At present the lighting extends only to the first three floors, but foundations have been laid and space provided for duplicating the engines and machines in readiness for lighting the upper floors. The switch-board contains some new features, and the main leads are arranged in nine distinct circuits, connecting various portions of the building, so that the whole or any part of the system is perfectly under the control of one man. An Ayrton and Perry's voltmeter and two ammeters are attached to the switch-board, and there is, in addition, a third small ammeter which enables the attendant to test either of the nine separate circuits at will. The installation is altogether an excellent specimen of its class. Messrs. Henry Lea and Thornbery, of Birmingham, were the consulting engineers to the bank.

TRANSFORMER PATENTS IN AMERICA.—A REMARKABLE CORRESPONDENCE.—The position of the Westinghouse Company, who claim the sole right to employ alternate current transformers "on a closed circuit" in the United States, has, no doubt, been somewhat strengthened by the recent recognition of their claims on the part of the Thomson-Houston Company. It is, however, to be feared that the question will not be settled without extending still further the long catalogue of electrical patent litigation. Meanwhile, we have to record what appears on the surface to be a decidedly praiseworthy attempt on the part of the United States Company to render as short and simple as possible the proceedings which they appear to think inevitable. From the singular correspondence now published by the *New York Electrician and Electrical Engineer* we compile the following condensed version. It will be understood that, although conveying the essence of the letters, we are not reproducing the language verbatim throughout:—

Letter I.—Solicitors of U. S. Co. to Solicitor W——st——e Co. Your clients insert advertisements making claims which our clients don't admit. Enclosed you will find a statement of what we are doing, what we intend to do, and how we do it. Now, then, what have you to say, gentlemen? "We don't want to fight, but by," &c., &c. We deem it proper to say that in case you do not bring a suit at present we shall feel at liberty to make use of this correspondence in any subsequent litigation against our clients on the patents referred to.

Letter II.—Solicitor No. 2 to Solicitor No. 1. Not quite made up our minds at the present moment, but rather think we shall go for you. The course adopted by your client in regard to this matter, and its abandonment of the system of electrical distribution which it has always heretofore used, in order to adopt the alternating system, which we have not only patented but actually created in this country, is hardly to be justified by the laboured and unusual notice which you have favoured us with.

Letter III.—W——st——e Co. to U. S. Co. Thanks for candid admission, though this does not of itself atone for your flagrant disregard of our rights. We should have thought your conduct more fair if you had written before you started the business, and not when, after a "secret and systematic preparation," you are already opposing us in the field. We shall make use of every lawful means at our command to vindicate our rights. In conclusion, we would ask you to contrast your behaviour in this matter with our own conduct in reference to your three-wire patent, when, without question, and at considerable expense and trouble, we changed several plants rather than have the appearance of infringing upon your rights.

Letter IV.—U. S. Co. to W——st——e Co. This is very cruel. We went out of our way to be polite and attentive, and now you positively threaten us. And it is quite a mistake on your part to suppose that we have admitted an infringement of your patent claims; we only admit an infringement of the claims in your *advertisements*. We don't admit that we have abandoned our previous system, because we have not done so, and don't mean to. And we don't admit that we have done anything "secret," though we confess to being highly "systematical" in our procedure. As to the G. G. system you speak of, we would not have anything to do with it at any price. Perhaps you are not aware that we have secured the patent rights in this country of a certain Paul Jablochkoff. If you will just come round we shall be delighted to show you exactly what we are doing, and may possibly surprise you not a little.

Letter V.—W——st——e Co. to U. S. Co. You have indeed surprised us very much. Now that we have had the pleasure of inspecting your apparatus we fully comprehend that your devices and arrangements are not of a character to cause us any serious uneasiness, at least until they have undergone radical change. So sorry to have made mistake of taking you seriously. Hoping, however, to hear from you again some day.—Yours respectfully, (Signed) G. W., JR.

This is really a very funny episode, but it is scarcely to be supposed that the matter will actually be allowed to end here. Meanwhile it is but just to recognise that the correspondence does both parties infinite credit.

THE ELECTRIC LIGHT AT THE ADELAIDE JUBILEE INTERNATIONAL EXHIBITION, 1887.—The following description of this installation appears in our contemporary the *Engineer*:—"The promoters of the Adelaide Exhibition having called for tenders for lighting the buildings, to which several electrical firms responded, a tender from the Australasian Electric Light, Power and Storage Company, of London and Sydney, was accepted, and a contract entered into with the above company for supplying 140 arc lamps and 210 incandescent lamps. Although not a very extensive installation when compared with some of those we are used to see on this side of the globe, it is by far the largest arc light installation that has up to the present time been attempted in Australasia. The motive power for driving all the electric light plant is supplied by Messrs. Robey and Co.'s steam engines, through their agents, Messrs. Harrold Brothers, of Adelaide, whose firm are also the sole agents in South Australia for the Australasian Electric Light, Power and Storage Company. The plant, which is located at the south-east corner of the machinery hall, covers an area of 80ft. by 60ft.; the space is neatly railed off, so as to permit of a thorough inspection, but at the same time keeping the onlookers at a safe distance from the numerous pulleys, belts, and dynamos. The electric plant comprises ten No. 7A Brush arc dynamos, each of 8,000 watts capacity; one No. 6 convertible Brush arc dynamo of 6,000 watts capacity.

Digitized by Google

This machine can, by means of an ingenious switch, be made to give a current of 10 amperes and 600 volts, or 20 amperes and 300 volts, which makes it a very useful machine for charging accumulators when not employed for working arc lights. The incandescent plant comprises three C² Brush Victoria dynamos, each of 8,000 watts capacity; one Edison-Hopkinson dynamo of 7,800 watts; and one Edison dynamo of 5,000 watts. The dynamos are fixed in two parallel lines and secured to heavy baulks of Oregon timber, which are securely bolted to transverse sleepers buried in 3ft. of concrete. The dynamos are driven from a line of countershafting 70ft. in length by 4in. diameter, supported on substantial wooden trestles. To avoid the risk of a total failure of the light due to an accident to an engine or dynamo the shafting is cut into several sections, each section driven respectively by the following engines of Messrs. Robey and Co.'s manufacture, viz., one 16 horse-power nominal portable engine, one 20 horse-power nominal portable engine, one 20 horse-power nominal compound semi-fixed engine, fitted with automatic expansion gear, one 16 horse-power nominal semi-fixed engine, one 12 horse-power nominal semi-fixed engine, and one 30 horse-power nominal horizontal engine fitted with Prôell's automatic expansion gear. There are ten arc circuits, four having 13 Fyfe-Main lamps in each and six running 15 to 16 Brush lamps, each making a total of 145 arc lights. Each arc circuit is provided with a switch, which is used for closing the circuit when the dynamos are started. As there is, however, always some difficulty in breaking a high-tension arc circuit through an arc forming across the contact surface of the switch, the field-magnet coils of the Brush dynamo are each connected to a separate switch on the switch-board. This switch, upon being closed, short circuits the field-magnet coils of its particular machine, with the result that in a few seconds the dynamo ceases to generate any current. The main circuit switch can now be opened without, of course, any sparking. Each of the incandescent light circuits is controlled by a main switch, and is also provided with the usual safety cut-outs. Cardew voltmeters are connected to the circuits of each of the incandescent dynamos. Two of Ayrton and Perry's direct-reading spring voltmeters are provided, one registering from four to twenty amperes for the arc circuits, the other registering up to 200 amperes for the incandescent circuits. In all 141 arc lamps and 211 incandescent lamps are employed. There are also several arc and incandescent lamps supplied to some of the exhibitors, which brings the total up to 145 arc and 266 incandescent lights. About eight miles of cable have been used for running the various circuits, which have been arranged, as far as possible, so that no particular building is lighted entirely from one dynamo, so that in case of a break-down the place would not be plunged into total darkness."

THE NEW CABLE LINE BETWEEN PORTHCURNO AND ZANTE.—The Eastern Telegraph Company, which is always quietly and steadily advancing, have just completed a very important addition to their already extensive system by laying cables between Porthcurno, *viâ* Lisbon, Gibraltar and Malta, and Zante, the whole work having been carried out by the Telegraph Construction and Maintenance Company. The first section between Porthcurno and Lisbon was laid from the ss. "Scotia," between the 11th and the 21st July. The total length is 891·83 n. miles, and consists of five different types of cable—viz., first, the heavy shore ends, 180lb. to n.m. sheathed with 10 No. 00 gal. iron wire; secondly, heavy intermediate, 10 No. 2 G.I.W.; thirdly, a lighter type, consisting of 10 No. 6; fourthly, a still lighter type, with 12 No. 13 homo. iron; and lastly, the deep sea type, of 9 No. 13 homo. iron. The two heaviest types are served with jute yarns and Clark's compound, and all the others with Johnson and Phillips's patent tapes and compound. The line was laid from Porthcurno to Lisbon, and cut and buoyed about 15 miles from Lisbon and the shore ends laid out from shore to this point. The total length of deep sea was 665 miles. The greatest depth passed through was 2,700 fathoms, and the line passes well to the westward of existing cables. Through the careful selection of the route by the company's general manager and their engineers, Messrs. Clark, Forde and Taylor, it is laid in a more uniform depth than the cables previously put down between England and Portugal. The line from Lisbon to Gibraltar was commenced on the 22nd, and finished on the 27th of July. The total length is 337 n. miles, and consists of four types of cable similar to those of the last section described. The maximum depth passed over was about 1,000 fms., and the mean about 145 fms. The Gibraltar and Malta section was commenced on 27 h of September from the ss. "Scotia," and paid out to within about twenty miles of Malta, and the end buoyed. The "Scotia" then proceeded to Zante, and commenced on the 8th of October to lay in the direction of Malta, and buoyed the end about six miles from that place on the 10th October. The "Scotia" then went into Malta and laid out the shore ends, completing the Malta-Zante section on the 11th inst. The "Scotia" next laid the shore end of the Gibraltar-Malta section, completing this section on the 12th inst. The reason for thus leaving the Gibraltar-Malta section buoyed for some days was on account of there being cholera at Malta, which would, had the ship entered Malta Harbour, have rendered her liable to quarantine detention at Zante. The length of the Gibraltar-Malta cable is nearly 1,126 n. miles, consisting of five types, four of which are similar to those described, and one type sheathed with 12 No. 9 G.I.W. The length of the Malta-Zante section is 374 n. miles. The core of this section is composed of 130lb. of copper and 130lb. of G.P. to the n. mile, and the types, as regards the sheathing, are similar to those described. We have not given the lengths used of each particular type, but most of the heavy shore ends extend into about 20 fms., and the deep sea type commences in depths varying between 200 and 400 fms. The core of all sections between England and Malta consists of 200lbs. of copper and 180lbs. of gutta percha per knot, that of the cable between Malta and Zante consists of 130lbs. of copper and 130lbs. of G.P. The present practice is tending towards increasing the weight of copper relatively to that of the insulator, which gives higher speeds for a given cost of core. The insulation resistance of the various sections at the fifth minute after laying was as follows:—

	At Sea Temp. Megs. per N. Mile.	Reduced to 75° F. and Atmospheric Pressure. Megs. per N. Mile.
Porthcurno and Lisbon ...	12,618	618
Lisbon and Gibraltar	2,571	565
Gibraltar and Malta.....	5,714	—
Malta and Zante	6,893	—

The whole work has been carried out with great promptitude and success, the last expedition having been only away five weeks and the first only three weeks. Mr. Lucas was in charge on the part of the Construction Company and Mr. Forde on the part of the firm of Clark, Forde and Taylor, engineers to the Eastern Telegraph Company. The company have thus ensured another line between England and Malta and on to Zante, and only touching at one foreign port, viz., Lisbon, and the line has been worked through admirably direct from Porthcurno to Gibraltar.

JEHL AND RUPP'S SYSTEM OF CONTINUOUS-CURRENT TRANSFORMERS.

The system of continuous-current conversion by Messrs. Jehl and Rupp, of Brünn, described below, possesses many instructive features, and also evinces a considerable amount of ingenuity.

The inventors start by considering the case of a simple iron ring wrapped with two distinct windings, as shown in Fig. 1, and the disposition of the field, as indicated by the dotted lines, and its ordinary inductive effects upon the secondary circuit are described. The want of magnetic continuity in a simple ring when excited from diametrically opposite points on the primary winding would, however, entirely cripple such an apparatus for use as a transformer, even though the necessary pulsations or alternations of current were obtained. This consideration has led to the adoption of a second revolving part in the apparatus, the introduction of which, as will be readily seen from the figures, renders the magnetic current as complete as that obtained in the ordinary dynamo. This part of the machine may consist of either of the following, viz. :—(1.) A second laminated iron ring supported on a spindle, and running either within or alongside the first (Fig. 2). (2.) A

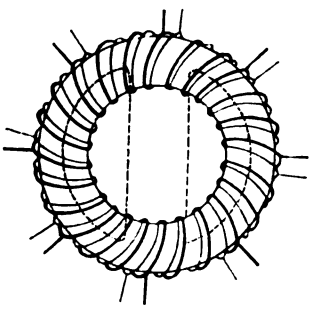

Fig. 1.

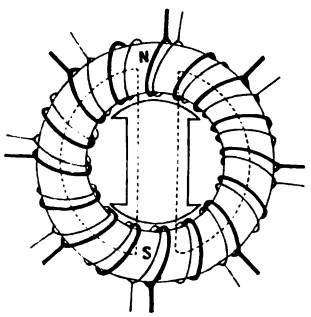

Fig. 4.

rotating drum in place of the ring (Fig. 3). (3.) A shuttle or H armature in place of the drum (Fig. 4). In each and all of the above arrangements it will be seen later that the revolving part corresponds to the field-magnets in an ordinary motor, and may be utilised to receive a part of the winding. It can, however, be also looked upon as a polarised armature, and for convenience it will here be termed the armature.

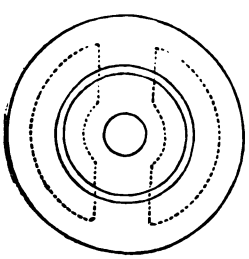

Fig. 2.

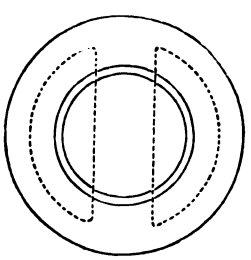

Fig. 3.

The object is now to send either a pulsating or alternating current through the primary and to collect the induced current from the secondary circuit. This is performed in the apparatus before us by means of what the inventors term a distribution commutator, half of which is illustrated in Fig. 5. Each point of access on both the secondary and primary circuits, indicated in the figure by the thick and fine lines respectively, is connected to a bar of the commutator, which for convenience in diagram is shown as if it were unrolled and laid flat upon the paper. These collecting bars are arranged in pairs, against each of which a separate brush makes momentary contact as the commutator revolves. Since these brushes are respectively connected with the several sections on the fixed ring the bars are arranged step fashion, as shown in the diagram, so that current is not taken from more than one diameter of the ring at any given time.

Two ordinary Gramme collectors are also fixed on the same spindle, one for each circuit, the bars of which are connected to the step bars aforesaid. A single pair of brushes press against each of these collectors, which respectively conduct the current to the primary circuit from the line and from the secondary to the lamp circuit. The whole commutator is on the same spindle with the armature, and is rotated with the latter at a uniform speed by some external source of mechanical power. It will thus be seen that by the action of the apparatus the fixed ring is successively polarised at diametrically opposite points, advancing in jerks by the angular distance corresponding to a section of the winding. A pulsating magnetic flux is thus generated in opposite directions through the fixed ring, the circuit being always completed by the armature, which is in synchronous motion with these pulsations. Under these circumstances an electric current of like pulsating character is generated in the secondary circuit, but which by means of the commuting arrangement above described, leaves the large brushes on the Gramme collector in the same state of continuity as the primary. A really clever device is adopted in the case of transformers connected in series, as follows :—Both rings, or the fixed ring and rotating drum, are wound with primary wire, there being no secondary winding at all. The secondary circuit is connected to the same points on the apparatus as the line wire from the central station—viz., to the large brushes on the Gramme collector. Since only one winding is used, a single commutator like that shown in Fig. 5 is sufficient, the step bars, with the Gramme collector bars, being connected to the different sections of the primary. Now, on rotating the commutator and armature, a counter E.M.F., due to the self-induction of the primary, will be set up, the current from which is taken off the large brushes and utilised in the lamp circuit. This E.M.F. will be constant, providing that the current in the primary is constant, and the plan is therefore only applicable when the transformers are used in series on a constant current circuit. It will be evident that the weak point in this device is the commutator with its numerous brushes, but we take it that this feature is susceptible of some practical improvement.

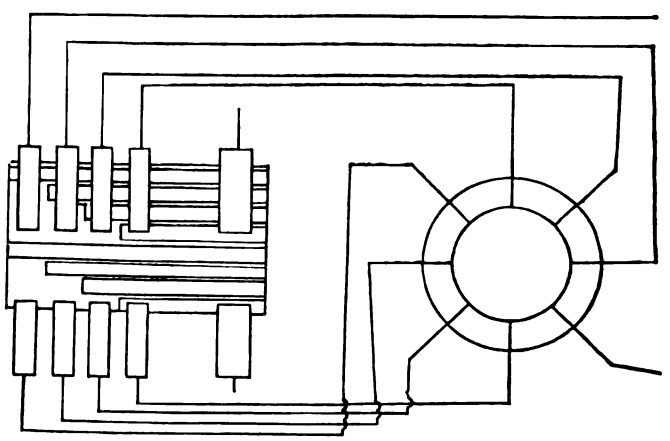

Fig. 5.

It is also suggested by the inventors that by suppressing the distribution commutator altogether, the apparatus may be employed as an alternating current transformer, but it needs little further examination to disclose the fact that this design cannot compare favourably, in point of economy, at any rate, with other transformers already in the market.

AN ELECTRO-THERMAL RECORDING TELEPHONE.

Since the time when Mr. W. H. Preece experimented with a diaphragm attached by its centre to a fine stretched wire of platinum, the possibility of reproducing speech by means of the thermal effects of a variable current in altering the tension of a fine wire has been placed beyond dispute. The instruments which we are about to describe are, however, we believe, the first illustrations of an attempt to turn this possibility to good account. Mr. Preece was, moreover,

Digitized by Google

content to employ an ordinary carbon transmitter for his researches, but Mr. W. E. Irish (of Cleveland, Ohio) has attacked the problem at both ends, and produced a thermal transmitter as well as a thermal receiver. It is true, once more, that a transmitter depending upon the variation of temperature, primarily due to sound waves, is not in itself entirely novel, inasmuch as Prof. Forbes has described an instrument based upon this principle. But the Irish transmitter is totally different from that of Prof. Forbes, and above and beyond all it is capable of permanently recording, and at any time reproducing articulate speech after the manner of the phonograph. Whether or not the apparatus is adapted for industrial employment, we are sure that our readers will not fail to arrive at the conclusion that it constitutes a triumph of inventive ingenuity and constructive skill.

As regards the transmitter the principle adopted by Mr. Irish is the following. A pointed loop of platinum wire is maintained at a red heat by a local battery. This rests against an insulating roller, from which, however, it is separated by a varnished strip of tin foil. The back end of the loop rests against the transmitting diaphragm, and is thus brought into more or less intimate contact with the tin foil. The foil itself travels over rollers, and the pressure of the red hot platinum burns larger and smaller holes upon the varnish. The transmitting strip thus prepared passes between two metallic rollers which are connected with the line and earth respectively.

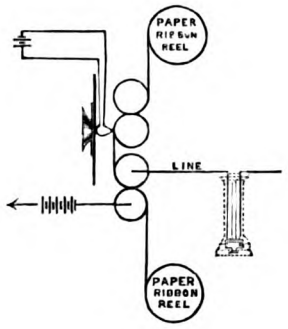

FIG. 1.

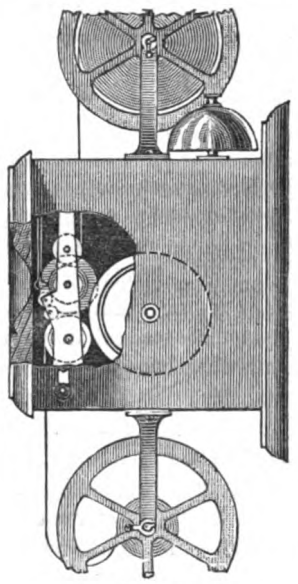

FIG. 2.

The following more detailed description is from the New York *Electrical World* :—

In the centre, at the back of an adjustable diaphragm, rests a wedge-shaped piece of platinum wire supported by two springs and resting with the thick end of the wedge against the centre of the diaphragm, while the point is directed inwards and lightly touches the ribbon in which the message is to be perforated. The ribbon behind the point passes over a drum which is recessed circumferentially in its centre, so as to offer no obstruction to the passage through the ribbon of the heated platinum point. This platinum point perforates the ribbon more or less according to its degree of heat, its shape and size, and the intensity of sound actuating the diaphragm. The louder or higher the pitch of the sound the deeper will be the penetration of the platinum point through the ribbon, and the larger in proportion will be the perforations. The perforated ribbon as it leaves the recessed drum is drawn between two other drums connected respectively to the line and one pole of the battery employed for transmitting ; the other pole being to ground, as shown in Fig. 1. The transmitting or last two mentioned drums are encircled by an elastic non-conducting material, made adhesive on the outer surface so as to hold the carbon powder with which they are served. Fig. 2 is a side elevation of the actual instrument.

The inventor has also employed with advantage, in lieu of the elastic covered carbon rollers, a vessel or funnel containing carbon granules. This funnel takes the place of the uppermost roller, and a flat conducting plate ,supported below the orifice in the bottom of the funnel, serves the purpose of a second roller, space being left sufficient to allow the perforated ribbon to travel freely between them. When the ribbon is drawn between the funnel and plate the carbon granules fall from the funnel into the perforations and make contact with the bottom plate.

It will be understood from the above that as the perforations in the insulated ribbon vary in size, in the same proportion will more or less carbon fall into them and the resistance of the circuit be varied. The larger the perforation the greater the space which will be occupied by the granules and the lower the resistance of the circuit ; and, as must necessarily follow, the smaller the perforations the less the space for the granules and the greater the resistance of the circuit. Mr. Irish, however, prefers the two elastic conducting drums, as illustrated, instead of the funnel and carbon granules for transmitting.

These drums make contact with each other through the perforations only, and so vary the resistance of the circuit accordingly. The interruptions and variations in the resistance of the circuit caused by the passage of the perforated ribbon between these contacts are made to reproduce on a receiving instrument at the distant end of the line the same sounds which actuated the diaphragm and perforated the ribbon at the transmitting end. The system permits of the making of a permanent record of all messages transmitted, and in such a manner that the messages may at any time thereafter be again transmitted by simply passing the ribbon between the contacts, or for local re-articulation or reproduction between the cold platinum point and its recessed drum. In either case the perforated ribbon is drawn between the contacts, or between the platinum point and recessed drum by the clockwork, as when used while speaking, the ribbon being first wound back off the lower on to the upper reel. When the message to be reproduced is on a filed ribbon, the ribbon is placed in the upper reel and wound off on an empty one placed below. Thus these instruments act as transmitters and reproducers of all messages previously sent on them. It will be seen that a local circuit is employed for heating the platinum while transmitting, but not for the receiving or reproduction or retransmission of a message.

The receiver most generally used in connection with this transmitter consists of a tube with an enlarged end for the diaphragm and an ear piece outwardly like an ordinary telephone receiver ; but here the similarity ends. A wire is stretched several times between the bottom of the receiver case and the diaphragm, each wire when doubled back being insulated from the next in such a manner as to cause the currents to travel each bend and the whole length of wire. The two ends of this wire are connected as usual to binding posts, to which also the line and ground wires are connected. The variations in the resistance and the interruption of the circuit caused by the difference of size or degree of the perforations, or their absence, cause the wire stretched in the receiver tube to expand and contract, correspondingly vibrating the diaphragm and reproducing the sounds given out at the distant end of the line. In this system of telephony the permanent and electro-magnets usually employed can be dispensed with, as well as carbon transmitters with diaphragms and tension regulators.

The transmitting part of this apparatus, according to the inventor, can be employed and gives excellent results as a phonograph. For this purpose it is found advantageous to use a somewhat stiffer stylus than the platinum one referred to for perforating the ribbon. The ribbon employed may be of especially prepared paper or metal foil well insulated.

The instrument described makes sound vibrations visible and produces a permanent record of them which can be stereotyped and printed from. It not only makes speech visible, but it is said to reproduce it in such quality of tone and clearness that persons acquainted with the speakers can recognise them by their voice.

INDEXES TO UNITED STATES PATENTS ON ELECTRICITY.—The United States Patent Office announces that Appendix No. 2 to the index to patents relating to electricity, covering the period of time from July 1, 1882, to June 30, 1883, has been issued, and is now for sale. These indexes, arranged alphabetically, numerically, and by classes, are completed to June 30th, 1883, and comprise the following volumes : — Vol. 1. Index to patents relating to electricity granted by the United States prior to June 30, 1881, with an appendix, July 1, 1881, to June 30, 1882. One volume, 250 pages. In paper covers, $3 ; bound, $5. Vol. 2. Appendix No. 2, July 1, 1882, to June 30, 1883. One volume, 50 pages. In paper covers, $1.50. Vol 3. Appendix No. 3, July 1, 1883, to June 30, 1884. One volume, 60 pages. In paper covers, $1.50. Vol. 4. Appendix No. 4, July 1, 1884, to June 30, 1885. One volume, 60 pages. In paper covers, $1.50.

NOTICE.

We beg to notify that all correspondence and contributions intended for this Journal should be in future addressed to THE ELECTRICIAN, 1, Salisbury-court, Fleet-street, E.C., instead of to Mr. C. H. W. Biggs, whose connection with it has ceased. We deem it right to add that no other change whatever has occurred or is contemplated in the proprietorship or management of this Journal.

UNDERGROUND WIRES IN AMERICA.

The hasty and peremptory action of some of the American municipalities in ordering the removal of overhead telegraph and telephone wires has not resulted very satisfactorily to any of the parties concerned. In this country, where the authorities have been far more lenient to the telephone companies—and, it may be added, the companies a little less defiant of the public—a long-threatened crusade against this aerial nuisance is still indefinitely postponed. Meanwhile the companies proceed with their work, asserting their legal rights wherever they are challenged, but generally with a due sense of their insecurity. That sooner or later these overhead wires will have to go underground, at all events in populous towns, there can be little doubt. But the respite they at present enjoy will perhaps prove advantageous if only for the warnings we may derive from American experience in the art of laying wires underground. We say warnings, for after perusal of the three or four papers on this subject from American sources reproduced in these columns to-day, our readers will see that there is not much to learn in that quarter, though there is a great deal to avoid. On this point we are inclined to agree with our New York contemporary and namesake in saying, that if the work of providing that city with a system of electric conductors be left in the hands of the present Board of Electrical Control—which is the Subway Commission under a different name—and under their control, the last state of New York, electrically speaking, will be worse than the first. Of the several conduit systems approved by the Board some few, says the New York *Electrician*, may prove serviceable for a long time; but all the work so far can only be regarded as tentative. Certain essential elements of the problem seem to have been scarcely considered at all, and there is no evidence of a well-planned scheme such as ought to have been in existence before the work was commenced.

These remarks of our contemporary are borne out by Mr. W. E. SARGENT'S paper on the underground telephone wires at Brooklyn, consisting of nineteen miles of cables. First of all, there was the difficulty of obtaining the sanction of the local authorities for the construction of the underground conduits; for, although the companies were forbidden to fly their wires overhead, no provision was made to afford them a decent burying place underground. This obstacle, however, at length being overcome, various patterns of conduits and troughs and cables had to be tried experimentally, and, we need hardly add, expensively. Nothing very definite has yet been arrived at; but, on the whole, the officers of the Brooklyn Telephone Exchange are inclined to the opinion that a conduit of creosoted wood, though neither air nor water-tight, is superior to the asphalte or concrete type of conduit—at all events, as made and laid in America. For our own part, however, we are still inclined to think that this conclusion would have to be modified if the wooden conduit be compared with a properly designed and carefully constructed conduit of the bituminous or possibly of the concrete type. The American conduits seem invariably to be laid down with such frantic haste that any system which requires careful workmanship seldom or never gets a fair chance. This, at least, is the impression we derive not only from Mr. SARGENT'S paper, but also from other sources of information. The iron pipe system, which gives such excellent results in the service of the Post Office in this country, does not seem to be much employed in America, though it is in use, amongst other places, at Chicago and at Boston. The cables laid in creosoted-wood conduits are nearly all lead-covered, and the greater durability of the alloy of lead and tin (the proportion of tin being very small) continues to be manifest.

In Chicago the results are not more encouraging than in Brooklyn, though they are somewhat different in character. We have tried our best to master Mr. E. B. SUNNY'S methods, but so much is taken for granted, and so much described in language which none but a native American can understand, that any opinion we may venture to form must be offered with extreme reserve. Evidently the workmen are ignorant of the elementary principles of laying subterranean wires; but the results are rather to Mr. SUNNY'S liking. The joints leak, and half a pint of water can be poured out of some of the "sleeves"; but the speaking seems to be rather the better for these eccentricities. Only when there is plenty of moisture about does the "cross talking" disappear, a continuance of dry, warm weather being almost fatal to the communication, which is then only carried on "by frequent repetitions and considerable discomfort." The nine cables concerning which this opinion is pronounced are said to be "new and in good condition." It does not surprise us, therefore, to be told immediately afterwards that there is a "fallacy in requiring manufacturers to furnish a cable of 300 to 800 megohms per mile," seeing that this degree of insulation cannot be maintained even if desired, and is not desirable, even if practicable,

Digitized by Google

because "cross talk is greater on a cable with a 'fancy' insulation than in one of a megohm." What is the precise difference between a "fancy" and a "megohm" we are not told; but we are led to suppose that both the writer and the subscribers to the Telephone Exchange at Chicago have a fancy for badly manufactured cables—a fancy which we should imagine they will have no difficulty in gratifying. Perhaps the incompetence of the workmen is not to be wondered at when the engineers talk in this fashion. A gleam of hope creeps in where it is said that a further "test indicates conclusively that we have used up all our margin, and that a slight addition to the length of the cables will make the connection of no commercial value." A still further test may possibly disclose the electrical "value" of the testing.

At Boston, according to Mr. DENVER, the Patterson system, which is the one also employed at Chicago, has given excellent results, perhaps for the same excellent reasons. According to English ideas the construction of the conduits and the enclosure of the cables are very roughly done. But that is probably no fault of Mr. PATTERSON or his system. We naturally turn, however, to his own remarks on "Joining Lead-Covered Cables." The whole process strikes us as calculated to make a British lineman's hair stand on end—always, supposing, as we said before, that we rightly interpret the language:—"The best way to make a splice is to strip the wires for an inch and a-half, bring them together, and, instead of making a long splice, bend them up, and then twist the ends together," leaving the joint at "right angles" to the conductor. What follows is equally startling, and may perhaps account for those curious tests to which we have adverted, and which lend some colour to the verdict of the New York technical journals that their underground electrical system has hardly yet passed the experimental stage. On the whole, we may congratulate ourselves that matters have not been pushed to a crisis with such precipitancy in this country. We agree with our American contemporaries that where numerous conductors of various kinds and sizes and for different purposes have to be provided for, some form of tunnel, large enough to admit of the wires and cables being hung in such a way as to be accessible at all points, is desirable, at all events for the principal routes. But in any case the undertaking demands the most careful consideration beforehand, and should be carried out "under the control of those who take a long look ahead and are more anxious to achieve a great public work carefully and thoroughly than to satisfy an unreasonable public clamour for burying all wires at once."

PARIS AND SCOTT'S CONTINUOUS-CURRENT TRANSFORMER AT THE NEWCASTLE EXHIBITION.

The continuous-current transformer of Messrs. Paris and Scott, at the Newcastle Exhibition, is now employed in lighting the model dwelling, and receives the current from the engine room through 900 yards of No. 12 copper wire. As the number of lamps in the villa is considerably below the capacity of the transformer, 64 lamps, besides some resistance, have been also placed in the circuit. The transformer is a two-pole machine, and two sets of coils are wound on the armature, the commutator for the primary coils being at one end of the shaft, that for the secondary at the other end. The primary coils contain four times as many turns of wire as the secondary, but of rather less than one quarter of the sectional area, so that the resistance of the primary wire is twenty times that of the secondary, and under normal conditions of working nearly the same amount of energy is absorbed in each. The field-magnet coils form a shunt to the secondary circuit, and the primary current is not employed in exciting the field. This causes the machine to hesitate before starting, and sometimes to start in the wrong direction. To obviate this Messrs. Paris and Scott propose to place a few turns of the primary wire upon the field-magnets. This will secure prompt starting in the proper direction, but will not sensibly interfere with the behaviour of the machine when fairly at work. The two sets of brushes for the primary and secondary currents respectively being independent, they may be set at any angle. Suppose the primary brushes to be set so as to make the machine run at the best advantage as a motor, then it is clear that if the secondary brushes were turned so as to be at right angles to the primary brushes, a big current might be sent through the secondary coils and the field-magnet coils, also excited from some external source, without offering any resistance to the rotation of the armature, and without any E.M.F. being produced by the rotation between the brushes of the secondary coil. Without going so far as this we may turn the secondary brushes into such a position that with a small resistance in the secondary circuit the E.M.F. in that circuit may be small, but the current very large—in fact, much more than four times the current in the primary coils—and yet the primary current may be quite capable of driving the machine at a high speed. Of course the product of the primary current and the E.M.F. between primary terminals—that is, the watts *in*—must exceed the product of the secondary current and the E.M.F. between its terminals, or the watts *out*, by an amount equivalent to the heat generated in both the armature coils and in the field-magnet, and the work required to overcome the mechanical resistance to the motion; but this is quite consistent with the current in the secondary circuit very much exceeding four times that in the primary, provided the E.M.F. be correspondingly reduced. In a test of the efficiency of the machine which has just been made the current in the secondary circuit was exactly four times that in the primary, the one being 42 amperes, the other 10·5 amperes. A voltmeter was employed having a resistance of 2,336 ohms. This was connected directly to the secondary circuit, and registered 74 volts. To the primary circuit it was connected through a resistance of 7,008 ohms, so that the same indication of the voltmeter corresponded to four times as many volts. This enabled the two readings to be taken in nearly the same part of the scale, and any error in the instrument was made of little importance. The voltmeter thus arranged registered 86 volts, corresponding to an actual E.M.F. of 344 volts. This represents a *commercial* efficiency of 86 per cent., the ampere meter employed in measuring the secondary current being inserted in the external circuit so as not to measure the exciting current of the field-magnets. By exerting considerable pressure on the brushes by hand the mechanical friction was very much increased, and the primary current was increased by an ampere, while the secondary current showed no change.

It will probably be very easy to control the brushes of the primary or secondary circuit automatically so as to keep the E.M.F. in the secondary circuit constant, whatever variations may take place in the E.M.F. of the primary. By shifting the primary brushes it was found possible to raise the E.M.F. of the secondary circuit until it was exactly one quarter of that of the primary. When the E.M.F. of the secondary circuit was then raised the whole output of the machine was necessarily increased, as no change was made in the number of lamps; but this was effected at the expense of efficiency, for the current in the primary circuit was increased in a greater ratio. In fact, when the E.M.F. of the secondary was thus raised to a maximum a considerable amount of sparking took place at the primary brushes, and the best position of the brushes to avoid sparking was found to be that which made the current in the secondary just four times that in the primary, so that there were the same number of amperes turns in each circuit. In one experiment when the speed of the engine had been reduced so that the E.M.F. of the primary was only 304 volts the brushes were set back until the E.M.F. in the secondary circuit was 76 volts. The current in the secondary was then 38 amperes, that in the primary 12¼ amperes,

Digitized by Google

showing an efficiency of only 78 per cent., instead of 86 per cent. as above. When the brushes were placed so that the E.M.F. in the secondary was 63, and that in the primary 272 volts, the currents were respectively 38 and 10·25 amperes, showing an efficiency of nearly 86 per cent. The highest efficiency obtained in any experiment was 87½ per cent., when the currents were respectively 42 and 10½ amperes, giving the same number of ampere turns in each circuit, and the volts were respectively 70 and 320 ; but this figure is probably a little in excess.

The high tension or primary coils on the armature have a resistance of 1·45 ohm, the low tension coils about ·07 ohm. The field-magnet coils forming a shunt to the secondary circuit have a resistance of 49·2 ohms. If we take the case mentioned above, where the currents were respectively 42 and 10½ amperes and the E.M.F. 74 and 344 volts, we have

Watts absorbed in primary	3,612
Watts obtained in secondary	3,108
Watts wasted in heating primary coils	160
Watts absorbed in field-magnet coils	111
Watts absorbed in heating secondary armature coils	132

Leaving a deficiency of only 110 watts for driving the machine. There is thus a loss of 4·4 per cent. in the primary armature coils, 3 per cent. in the field-magnet coils, and 3·66 per cent. in the secondary armature coils, while rather less than 3 per cent. of the energy received is employed in doing the mechanical work of driving the armature against friction. The current in the secondary armature coils is of course that in the outer circuit, together with the exciting current. It is clear, from the above figures, that there is practically no loss by Foucault currents.

It was found that when the secondary brushes were turned through a considerable angle a great amount of sparking was produced, so that measurements have not yet been made with the primary brushes in their best position to drive the machine as a motor, and the secondary brushes turned through an angle so as to considerably reduce the E.M.F. of the secondary current.

THE PROPOSED ASSOCIATION OF ELECTRICAL ENGINEERS.

In our next week's issue we hope to be able to indicate more precisely the preliminary steps which it may then be thought desirable to take in respect to the proposed Association of Electrical Engineers. Our readers will of course agree that this is a matter in which it is desirable to remember the proverb, *festina lente*. Meanwhile we may note that our contemporary, *Industries*, devoted last week the whole of its leader to the subject, giving the project a very warm support. The majority of our correspondents whose letters do not appear will understand that nothing but want of space compels their omission, and that the greater the number of individual expressions of opinion which reach our hands, the stronger is our position with regard to subsequent action. Next week we shall probably furnish a list of the names of those firms who have expressed their adhesion to the general idea of the scheme. Meanwhile we select the following letters for publication :—

SIR : I have read with much interest the correspondence which has appeared on the subject of the proposed formation of an industrial association, as I recognise the necessity for combined action in regard to various matters of common interest to electrical firms.

A review of the correspondence, however, shows that while there is a general unanimity as to the desirability of an association of some kind being formed, there appears to be some divergence of opinion as to the precise objects and scope of the proposed institution. For this reason I agree with the suggestion which has been made that an outline scheme should be formulated for discussion at a public meeting.

If the association is to be successful and to possess the confidence of all sections of the trade, it is important that the objects to be attained should be clearly defined, and that the views of all should be adequately and fairly considered. As the representatives of the technical press possess by far the best means of ascertaining the views of the trade, there would be many advantages in their undertaking the initial work of drawing up a draft constitution, and I hope they can be prevailed upon to do this.

For my own part I fail to see that the objects of the association can be very numerous, if, as seems to be generally granted, the province of the existing societies is not to be encroached upon. That there is important and pressing work for the association to do cannot be denied, and if only a few of the many points suggested by Mr. Rawson are to be energetically pursued the need for a representative body is apparent. But the association should confine itself to matters requiring united action, *e.g.*, completing the work, already commenced, of securing a satisfactory amendment of the Electric Lighting Act, &c., and should not, by attempting to do impossible things, interfere with the natural growth and development of the industry. Such complex matters as "the maintenance of prices at a fair level," which are determined by the economic conditions of supply and demand, cannot well be settled by a resolution of a council, and had better be left to the operation of fair and legitimate competition.—Yours, &c., E. GARCKE.

112, Belvedere-road, Lambeth, S.E.,
24th October, 1887.

SIR : The proposal to establish an Association of Electrical Engineers, referred to in your journal and two of your contemporaries, is one that commends itself to us if it can be carried out properly.

Such an association should deal almost exclusively with the practical and commercial bearings of electric lighting and heavy electrical engineering, and the council or committee of management should be, we think, almost entirely composed of those commercially engaged in these industries. This being secured, the conditions of membership of the association need not necessarily be very strict.

The association should, we think, take a line entirely independent of either of the societies now in existence. The Society of Telegraph-Engineers has attained a prestige in its particular line which is too great to allow of a new society being affiliated to it without the latter being dwarfed. The new society must not be started under the ægis or protection of the old one, but stand by itself where it can have room to grow freely. The very constitution of the Society of Telegraph-Engineers and the atmosphere which surrounds it unfit it for starting the new society as it should be. Dealing until lately with telegraphy exclusively, and the telegraphs being the property of the State or of monopolist companies, the questions that have arisen for discussion have been purely scientific and not commercial or legislative. With the invention of the telephone and the glow lamp an endeavour was made to widen the area of discussion, but only as regards the "subjects" and not the method of their treatment. That society could not be modified to fill the present need without doing violence to itself and weakening its usefulness in its own peculiar work.

As regards the Dynamicables, we, and we think a good many others, hardly consider the work of this society as *serious*. Postprandial talking rarely leads to any practical issue, unless the object be to get funds for a charitable institution.

We hope the movement will succeed, and shall be glad to render any help in the matter that may be in our power.—Yours, &c., PATERSON AND COOPER.

London, October 20, 1887.

DEAR SIR : I shall be glad to co-operate with you in your endeavour to establish an Association of Electrical Engineers. * * * .—I am, dear sir, yours faithfully,

Culcheth, Bowdon, Cheshire, CHARLES LEVER
18th Oct., 1887.

DEAR SIR : We shall have great pleasure in joining your proposed Association of Electrical Engineers. We wish you all possible success for the undertaking, which promises much

Digitized by Google

good, not only to our particular branch of industry but also to the public at large. * * * .—Yours faithfully,

M. IMMISCH & Co.

London, N.W., Oct. 19th, 1887.

DEAR SIR: It is with great pleasure we observe how very favourably the proposal to establish an Association of Electrical Engineers is being received. We need hardly say how entremely glad we shall be to give it our support, and trust its formation will speedily be effected. * * * .—We are, yours faithfully,

KING, MENDHAM AND Co.

Narrow Wine-street, Bristol, October 22, 1887.

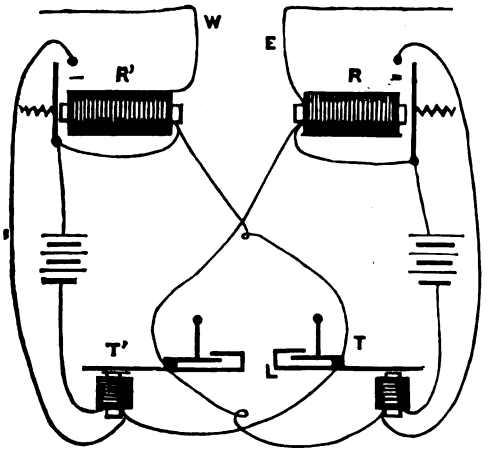
The following note from the *St. James's Gazette* is worth recording, as an illustration of the view likely to be taken of the movement by the outside public :—

An excellent suggestion, due to *The Electrician*, is being discussed with interest in the electric world. It is that there should be formed a new Association of Electrical Engineers, to include, not only that branch of the profession which already has a corporate existence in the Society of Telegraph-Engineers, but the whole of the electric light, motor, and other interests which have now reached so large a development. The arguments in favour of the proposal have been stated with much force by *The Electrician*; and, on behalf of the public outside the profession, we can only anticipate that such an association would do as much to raise electrical engineering with advantage to itself and to the public as has been done for their respective professions by the Institutes of Civil and Mechanical Engineers, the Iron and Steel Institute, and the Institute of Naval Architects.

A NEW REPEATER ARRANGEMENT.

The following note, by Mr. W. S. Cherley, appears in the New York *Electrical World* :—

"I have no doubt that most of your readers who are connected with the telegraph service have at some time experienced the annoyance incident upon unsatisfactory working of repeaters at intermediate repeater stations, probably caused by the lack of attention or the inability of the attendant to properly adjust them. In reflecting upon this matter I have devised a set of repeaters, using common instruments, which reduce the complication to a minimum.



New Repeater Arrangement.

"The action of the repeater, which consists of common relay and single transmitter, is as follows: East line opens, opening its transmitter T, which opens the west line. At the same instant the tongue of the transmitter makes contact with the lever, which closes the local circuit of the west transmitter T', so that the west relay cannot open it. Both relays R, R' work at the same time, but the local points of the west relay are cut out when the east transmitter is open. When the west line breaks the action is reversed. No extra local magnets or batteries are required. Half of the set can also be used for a single line on one side of a quadruplex."

CORRESPONDENCE.

RESISTANCE OF THE AIR SPACE IN DYNAMOS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. Fricker in his last article on Dynamo Design (*The Electrician*, October 21st, p. 494) refers to a conversation Mr. Kapp and I had at Manchester about the resistance of the "air-space" in dynamos, in which I pointed out that commercial copper is often more or less paramagnetic, and, consequently, that the presence of copper (namely, the armature-wire) in the so-called air-space might account in part for a fact Mr. Kapp told me he had observed—that the magnetic resistance in actual machines was considerably less than the thickness of the air-space had led him to expect. But I gave no figures, having made no measurements of the magnetic permeability of commercial copper, and the 100 per cent. guessed at in the article is not mine.

Although the cause I suggested to Mr. Kapp may have some influence, it must not be forgotten that, as J. and E. Hopkinson have shown (*Phil. Trans.*, Part I., 1886, p. 333), the resistance of the air-space is lessened by the conduction of lines of force through neighbouring air—that is, round the edges (so to speak) of the plate of air that lies directly between the pole-piece face and the armature. The effect of this is virtually to widen the plate of air, giving it an effective area greater than that of the pole-piece face.—Yours, &c., J. A. EWING.

University College, Dundee, Oct. 22nd, 1887.

[In this connection we may add that Mr. Ravenshaw, of the firm of W. T. Goolden and Co., who has been remarkably successful in calculating the characteristics of new types of dynamos, informs us in a private letter that he always employs Prof. Forbes' lemmas in determining the air resistance.—ED. *E.*]

SPRINGS ON TELEGRAPH LINES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Mr. Caws has not realised the conditions that determine the stability of a telegraph wire. It has sometimes to resist the stress of a constantly applied force like the heavy broken branch of a tree or the continued pressure of a gale of wind against a tube of frozen snow, and when either of these stresses exceeds the breaking stress of the wire, no such contrivance as he has designed will be of any service whatever in preventing the wire from breaking. The stresses for which his regulator is devised do not interfere with telegraphs in the least. They are, in fact, imaginary troubles.

His tension regulator, which is by no means novel, would only magnify the evil, for it would cause more snow to accumulate.—Yours, &c., W. H. PREECE.

General Post Office, Oct. 26, 1887.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I note in your last issue a description and sketch of a form of spring for telegraph wires patented, apparently, by Mr. Frank Caws.

Perhaps, as the subject is being further renewed since the British Association meeting, it would not be out of place, from an historical point of view, to mention that M. Bardonnaut, Directeur-Ingénieur of the French Postes et Télégraphes, in 1885 proposed a spring which would answer the same purpose, and which he calls a *sourdine*.

It was devised to be placed either between the wires and the insulator, as in Mr. Caws' system, or between the insulator pin and the telegraph post.

M. Bardonnaut appears to lay most stress on its qualities as a "deafener" to the humming noise due to vibration, rather than as a regulator to meet either any sudden forcible strain or the effects of the variation of temperature on the wires, which, I observe, is Mr. Caws' main object. The same springs would appear, however, to answer both requirements equally well. I have with me a description of M. Bardonnaut's proposed system. One of the vibrating springs he employs

Digitized by Google

is of the same pattern as that which takes part in the adjustment of the synchronism in Prof. Hughes's type printing instrument, as being peculiarly well adapted for the purpose. M. Bardonnaut's plan shows no alternative course for the current to pass along besides the springs of necessarily high resistance, as is provided by the bow connection in Mr. Caws' method; in this respect, therefore, Mr. Caws' arrangement is certainly markedly its superior.

M. Bardonnaut states that his system was tried in Toulouse, with the result that householders, who had previously complained of the noise from the wires connected to their houses (to the extent of threatening to take legal proceedings), pronounced that since the alteration there was an entire absence of any similar disturbance.

It is not altogether improbable, I should fancy, that such an idea of springs for telegraph wires may have occurred to the minds of other telegraph engineers at various times since the evolution of electro-telegraphy, but for some good reasons presumably it has never yet, I believe, been carried into practice in this country; or else the advantages of such a plan are found to be insufficient to warrant the expense of construction entailed thereby.—Yours, &c.,

October 26th, 1887. CHARLES BRIGHT, JUN.

ELECTRIC TRACTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We have read with great pleasure your highly interesting article in last week's *Electrician* upon certain electrical experiments carried out on a section of the North Metropolitan Tramway by the Elieson Electric Locomotive Company. Congratulation is due to that company for the measure of success attained, but, judging from the figures published in your article, we cannot help feeling that greater success, from a commercial point of view, is still in store for electrical traction.

The first question naturally asked by tramway companies will be the amount of capital required to equip the lines with electrical traction. It is needless to point out the inconvenience of adding to the capital account of a very large proportion of existing tramway companies, where the present traffic receipts barely pay dividends; a difficulty which would be increased in proportion as the capital is enlarged. Therefore, in all arrangements for electrical traction, the primary consideration should be the reduction of the initial cost of equipment.

The next question asked will be the weight of the rolling load to carry a specified number of passengers, the reduction of which must be a serious consideration in electrical traction.

Question number three will be the comparison in length of car and electric locomotive with that of tramcar and horses, compactness being of the highest importance in crowded streets.

One other inquiry will be—what are we to do with our present rolling stock?

The Electrical Traction Syndicate, of which I have the honour to be secretary, in all their arrangements have had the solution of the above four questions as their chief object; so taking the statements contained in your article as my text, I will answer these questions.

(1.) *Initial Expenditure.*—At page 495 you say, "under this system of separate locomotives it is necessary to have two to each car," and "an initial expenditure of about £1,100 per car, as against only about £400 for horses, so that to put the two systems on an equal footing in this respect the depreciation must be at only one-third the rate in the former case." Now, the average life of tramcar horses cannot be taken at much more than three years. This means a depreciation of 33 per cent., and thus, to balance the greater initial expenditure with locomotives, this electrical system would require a depreciation of only 11 per cent. *Can this be possible?* The E. T. Syndicate, on the other hand, reduce this initial expenditure of £1,100 by nearly one half. Their self-contained cars, carrying the same number of passengers, cost only about £600, in comparison with two locomotives valued at £1,150 and the car which they haul, say, at £160—in all £1,310. In our case there is only one change of accumulators per day, the change requiring no longer than four minutes, and each set of accumulators gives half a day's run of thirty-five miles.

(2.) *Weight of Rolling Load.*—We understand locomotive and loaded car weighs about 11½ tons, whereas for the same number of passengers our total rolling load *is less* than *eight* tons.

(3.) *Space Occupied on Road.*—With locomotive the length is greater than with horses, while with our self-contained car the ground occupied is actually only that required for the car.

(4.) *Present Rolling Stock.*—With our system the present rolling stock can be converted into electrical cars at an expense which will be nearly covered by the amount realised by the sale of the horses.

Stabling.—As regards storage room for locomotives, it is obvious that three times the space will be required where a car and two locomotives have to be put up instead of one self-contained car only.

Time Saved at Termini.—With locomotives time is lost by uncoupling, shunting, and re-coupling before starting, whereas with our cars we run in, and can instantly reverse for the return without a moment's loss of time.

The advantages set forth herein, in conjunction with the excellence of the Immisch motor, have solved not only the practical but the commercial success of our system.—Yours, &c.,

JOHN T. CARRINGTON, Secretary,
Electric Traction Syndicate (Limited).

Malden-crescent, Kentish Town, London, N.W.,
Oct. 26, 1887.

PROF. FORBES' TABLES.

Prof. Forbes has kindly furnished us with copies of his well-known tables for calculating the size of conductors, which will be found on the opposite page. These tables were first made known in the Cantor Lectures of 1885, and have now been recalculated in international units. We reprint the instructions for using these tables from our issue of October 16th, 1885:—

RULES FOR FINDING FROM GIVEN DATA THE SIZE OF THE MAINS REQUIRED.

Data required: Annual cost of electrical horse-power and percentage for interest and depreciation per annum, and cost of laying one additional ton of copper, the approximate size having been assumed.

Rule 1.—In Table B look down the column of cost for additional ton until you reach the given percentage allowed. Take out the number there indicated.

Rule 2.—In Table A look along the line with the given cost of horse-power until this number is found. The number at the head of that column is the section per 1,000 amperes in inches.

Rule 3.—If this section be largely at variance with the approximate one selected, use now this value for a second calculation.

ON ELECTRIC STREET CARS, WITH SPECIAL REFERENCE TO METHODS OF GEARING.*

BY A. RECKENZAUN, C.E.

(Continued from page 502.)

GRADIENTS.

The effect of gradients is a matter of simple calculation, and it must be provided for in designing and constructing a motor. We have calculated above that the minimum effective power for a six-ton car running at six miles an hour on the level is nearly two-horse power, exclusive of gear friction or any other waste. If we have to overcome a gradient of 1 per cent., for instance, the resistance due to gravity will be 22·4 pounds for each ton, or 134·4 pounds for the loaded car. Therefore we shall require about 4 horse-power to pull this car up a grade of

N.B.—The cost per horse-power per annum must be taken in the same units as the cost of conductor in Table (B). Shillings, francs, marks, or quarter-dollars are most convenient.

TABLE (B).

Rate of Interest.	Cost per Additional Kilogramme of Copper.																		Rate of Interest.
	1·2	1·3	1 4	1·5	1·6	1·7	1·8	1·9	2·0	2·5	3·0	3·5	4·0	5 0	6·0	7·0	8 0		
5	5·3	5·8	6·2	6·7	7·1	7·5	8·0	8·4	8·9	11	13	16	18	22	27	31	36	5	
7½	8 0	8·7	9·3	10	11	11	12	13	13	17	20	23	27	33	40	47	53	7½	
10	11	12	12	13	14	15	16	17	18	22	27	31	36	44	53	62	71	10	
12½	13	14	16	17	18	19	20	21	22	28	33	39	44	56	67	78	89	12½	
15	16	17	19	20	21	23	24	25	27	33	40	47	53	67	80	93	—	15	

N.B.—Cost of conductor must be taken in the same units as the cost per horse-power per annum in Table (A); shillings, francs, marks, or quarter-dollars are most convenient.

N.B.—If the cost of conductor is given in pounds sterling per ton, divide this number by 50 to obtain the results in shillings per kilogramme.

Example.—Conductor costs 2·0 francs per additional kilogramme of copper. Rate of interest is 10 per cent. The auxiliary number found from these numbers in Table (B) is 18. If a horse-power costs 250 francs per annum, looking along this row in Table (A), the auxiliary number 18 is between 1·8 and 1·9 square centimetres per 100 amperes.

1 in 100. With a 2 per cent. grade we must have about three times the power used on level roads, and, roughly speaking, each per cent. of grade involves as much energy as the propulsion of a given weight over a horizontal road, if the speed is to be kept constant. On steep grades, however, it is customary to run a little slower, whereby some of the energy is saved; but for a car of the above weight, if it has to overcome grades of 4 per cent., it will not be safe to have less than eight horse-power available upon the driving axles. In addition to this the motor has to supply the power which is unavoidably wasted in the gearing used for transmitting motion from the armature shaft to the car axle. An ordinary street car wheel of 30in. diameter has to revolve at least 77 times in the minute, in order to traverse a distance of seven miles an hour. Up to the present time no one has succeeded in constructing an electric motor of reasonable dimensions, weight, and efficiency to work at such a low speed. Most of the existing motors revolve at from six to twelve times the above velocity ratio, therefore it became necessary to introduce speed-reducing appliances between the motor and the driving axles.

GEARING

The problem of devising suitable gearing for street cars carrying their own motor has been and is still one of the greatest importance, and I propose now to offer a few remarks with reference to this subject by citing some examples which came under my own observations. The conditions to be satisfied are by no means simple, and it is somewhat difficult to arrange them in their order of merit. Most engineers endeavour to retain the recognised dimensions of street cars, because great deviations therefrom involve many inconveniences, and it is wise to adhere as much as possible to the rules which have been established by custom, convenience and general utility. The fact that most of the street cars in all parts of the world are similar in shape indicates forcibly that a particular pattern satisfies the demand. When taking that popular pattern of car and adapting it to our electrical and mechanical apparatus, we find that the space at our disposal underneath the floor and between the axles is meagre and extremely limited. Within this small compass we have to fix the gearing which has to give the highest possible return of a given power: it has to be strong, durable, yet light in weight; noise and vibration have to be carefully avoided; the mechanism must be simple, certain in its action, protected from wet and dirt, and, finally, of reasonable cost. How to combine all these virtues has been the study of every engineer who has made electrical traction his serious study.

STEEL SPIRAL CORDS.

In regard to my own observations, one of the prettiest kinds of gearing in actual use is that on one of the cars of the Berlin Lichterfeld Electric Tramway, which was constructed six and a-half years ago by Messrs. Siemens and Halske. This car has a capacity for 24 passengers; it weighs when empty 3·2 tons, and makes a speed of 12 miles an hour. The electric motor is fastened under the floor in the centre of the car, having its shaft parallel to the axles. On the motor shaft is a small cast-iron pulley, which has 27 V-grooves on its rim, and within these grooves work an equal number of spiral wire cords, which transmit the motion to both axles of the four-wheeled car. The axles carry the large pulleys, one of which has 13 V-grooves on its circumference, and the other 14 grooves corresponding with those on the pulley on the motor

is of the same pattern as that which takes part in the adjustment of the synchronism in Prof. Hughes's type printing instrument, as being peculiarly well adapted for the purpose. M. Bardonnaut's plan shows no alternative course for the current to pass along besides the springs of necessarily high resistance, as is provided by the bow connection in Mr. Caws' method; in this respect, therefore, Mr. Caws' arrangement is certainly markedly its superior.

M. Bardonnaut states that his system was tried in Toulouse, with the result that householders, who had previously complained of the noise from the wires connected to their houses (to the extent of threatening to take legal proceedings), pronounced that since the alteration there was an entire absence of any similar disturbance.

It is not altogether improbable, I should fancy, that such an idea of springs for telegraph wires may have occurred to the minds of other telegraph engineers at various times since the evolution of electro-telegraphy, but for some good reasons presumably it has never yet, I believe, been carried into practice in this country; or else the advantages of such a plan are found to be insufficient to warrant the expense of construction entailed thereby.—Yours, &c.,

October 26th, 1887. CHARLES BRIGHT, JUN.

ELECTRIC TRACTION.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: We have read with great pleasure your highly interesting article in last week's *Electrician* upon certain electrical experiments carried out on a section of the North Metropolitan Tramway by the Elieson Electric Locomotive Company. Congratulation is due to that company for the measure of success attained, but, judging from the figures published in your article, we cannot help feeling that greater success, from a commercial point of view, is still in store for electrical traction.

The first question naturally asked by tramway companies will be the amount of capital required to equip the lines with electrical traction. It is needless to point out the inconvenience of adding to the capital account of a very large proportion of existing tramway companies, where the present traffic receipts barely pay dividends; a difficulty which would be increased in proportion as the capital is enlarged. Therefore, in all arrangements for electrical traction, the primary consideration should be the reduction of the initial cost of equipment.

The next question asked will be the weight of the rolling load to carry a specified number of passengers, the reduction of which must be a serious consideration in electrical traction.

Question number three will be the comparison in length of car and electric locomotive with that of tramcar and horses, compactness being of the highest importance in crowded streets.

One other inquiry will be—what are we to do with our present rolling stock?

The Electrical Traction Syndicate, of which I have the honour to be secretary, in all their arrangements have had the solution of the above four questions as their chief object; so taking the statements contained in your article as my text, I will answer these questions.

(1.) *Initial Expenditure.*—At page 495 you say, "under this system of separate locomotives it is necessary to have two to each car," and "an initial expenditure of about £1,100 per car, as against only about £400 for horses, so that to put the two systems on an equal footing in this respect the depreciation must be at only one-third the rate in the former case." Now, the average life of tramcar horses cannot be taken at much more than three years. This means a depreciation of 33 per cent., and thus, to balance the greater initial expenditure with locomotives, this electrical system would require a depreciation of only 11 per cent. *Can this be possible?* The E. T. Syndicate, on the other hand, reduce this initial expenditure of £1,100 by nearly one half. Their self-contained cars, carrying the same number of passengers, cost only about £600, in comparison with two locomotives valued at £1,150 and the car which they haul, say, at £160—in all £1,310. In our case there is only one change of accumulators per day, the change requiring no longer than four minutes, and each set of accumulators gives half a day's run of thirty-five miles.

(2.) *Weight of Rolling Load.*—We understand locomotive and loaded car weighs about 11½ tons, whereas for the same number of passengers our total rolling load *is less* than *eight* tons.

(3.) *Space Occupied on Road.*—With locomotive the length is greater than with horses, while with our self-contained car the ground occupied is actually only that required for the car.

(4.) *Present Rolling Stock.*—With our system the present rolling stock can be converted into electrical cars at an expense which will be nearly covered by the amount realised by the sale of the horses.

Stabling.—As regards storage room for locomotives, it is obvious that three times the space will be required where a car and two locomotives have to be put up instead of one self-contained car only.

Time Saved at Termini.—With locomotives time is lost by uncoupling, shunting, and re-coupling before starting, whereas with our cars we run in, and can instantly reverse for the return without a moment's loss of time.

The advantages set forth herein, in conjunction with the excellence of the Immisch motor, have solved not only the practical but the commercial success of our system.—Yours, &c.,

JOHN T. CARRINGTON, Secretary,
Electric Traction Syndicate (Limited).

N.B.—Cost of conductor must be taken in the same units as the cost per horse-power per annum in Table (A); shillings, francs, marks, or quarter dollars are most convenient.

N.B.—If the cost of conductor is given in pounds sterling per ton, divide this number by 50 to obtain the results in shillings per kilogramme.

Example.—Conductor costs 2·0 francs per additional kilogramme of copper. Rate of interest is 10 per cent. The auxiliary number found from these numbers in Table (B) is 18. If a horse-power costs 250 francs per annum, looking along this row in Table (A), the auxiliary number 18 is between 1·8 and 1·9 square centimetres per 100 amperes.

1 in 100. With a 2 per cent. grade we must have about three times the power used on level roads, and, roughly speaking, each per cent. of grade involves as much energy as the propulsion of a given weight over a horizontal road, if the speed is to be kept constant. On steep grades, however, it is customary to run a little slower, whereby some of the energy is saved; but for a car of the above weight, if it has to overcome grades of 4 per cent., it will not be safe to have less than eight horse-power available upon the driving axles. In addition to this the motor has to supply the power which is unavoidably wasted in the gearing used for transmitting motion from the armature shaft to the car axle. An ordinary street car wheel of 30in. diameter has to revolve at least 77 times in the minute, in order to traverse a distance of seven miles an hour. Up to the present time no one has succeeded in constructing an electric motor of reasonable dimensions, weight, and efficiency to work at such a low speed. Most of the existing motors revolve at from six to twelve times the above velocity ratio, therefore it became necessary to introduce speed-reducing appliances between the motor and the driving axles.

GEARING

The problem of devising suitable gearing for street cars carrying their own motor has been and is still one of the greatest importance, and I propose now to offer a few remarks with reference to this subject by citing some examples which came under my own observations. The conditions to be satisfied are by no means simple, and it is somewhat difficult to arrange them in their order of merit. Most engineers endeavour to retain the recognised dimensions of street cars, because great deviations therefrom involve many inconveniences, and it is wise to adhere as much as possible to the rules which have been established by custom, convenience and general utility. The fact that most of the street cars in all parts of the world are similar in shape indicates forcibly that a particular pattern satisfies the demand. When taking that popular pattern of car and adapting it to our electrical and mechanical apparatus, we find that the space at our disposal underneath the floor and between the axles is meagre and extremely limited. Within this small compass we have to fix the gearing which has to give the highest possible return of a given power: it has to be strong, durable, yet light in weight; noise and vibration have to be carefully avoided; the mechanism must be simple, certain in its action, protected from wet and dirt, and, finally, of reasonable cost. How to combine all these virtues has been the study of every engineer who has made electrical traction his serious study.

STEEL SPIRAL CORDS.

In regard to my own observations, one of the prettiest kinds of gearing in actual use is that on one of the cars of the Berlin Lichterfeld Electric Tramway, which was constructed six and a-half years ago by Messrs. Siemens and Halske. This car has a capacity for 24 passengers; it weighs when empty 3·2 tons, and makes a speed of 12 miles an hour. The electric motor is fastened under the floor in the centre of the car, having its shaft parallel to the axles. On the motor shaft is a small cast-iron pulley, which has 27 V-grooves on its rim, and within these grooves work an equal number of spiral wire cords, which transmit the motion to both axles of the four-wheeled car. The axles carry the large pulleys, one of which has 13 V-grooves on its circumference, and the other 14 grooves corresponding with those on the pulley on the motor

Digitized by Google

shaft. The wheel base is five feet nine inches, consequently there is only a distance of two feet ten and a-half inches between the centres of the connected pulleys.

The cords are made of a pair of steel wires wound closely upon a mandrel of about $\frac{1}{8}$in. in diameter, and when this mandrel is withdrawn there remains a stiff, yet flexible spiral, whose external diameter is scarcely $\frac{7}{32}$ of an inch. When cut to the proper length these cords are stretched over the grooves and connected at the ends by means of steel eyes and a steel link. Experiments made with this gear showed that eight spiral cords suffice for transmitting the power to the axles when the car was full of passengers, and as there are actually twenty-seven cords the margin of safety was deemed more than sufficient. It is a pleasure to ride on this car; there is no noise or vibration, and I was told that the spirals last a long time if carefully adjusted; but this method of transmission is not sufficiently positive to warrant its application on steep grades. On this line there is no grade of over 1 per cent. rise.

CHAIN GEARING.

The second car on the Lichterfeld tramway, which, by the way, must be regarded as the oldest line in the world as far as continuous successful operation is concerned, has chain gearing. The motor shaft is provided with a small toothed wheel, and one of the axles carries a large wheel with teeth to correspond to the gaps in the pitch chain links. This mode of transmission causes some noise and vibration, and this car runs slower than the other with same amount of energy. This is accounted for by the greater friction on the surface of the teeth, as well as by the bending and unbending of the link joints; there is, besides, a constant probability of the comparatively heavy chain being thrown off tangentially by centrifugal force. But this kind of gearing furnishes an absolute or positive motion, which cannot be relied on by methods depending upon frictional adhesion alone.

Some four years ago I applied two pitch chains, four toothed wheels and countershaft for propelling a heavy storage battery car in London. The chains were of steel and substantially made; the wheels of phosphor-bronze correctly shaped. I found that the chain on the fast running, first-motion shaft, rattled considerably. This chain stretched a little, when the links began to ride upon the points of the teeth, and eventually broke the teeth of the small wheel on the armature shaft. Previous to that I employed some other gear, which will be mentioned shortly.

Mr. Trail, the manager of the Portrush electric railway in Ireland, has been more fortunate than I with chain gear, but he is not perfectly satisfied, and he is now experimenting with something else. Pitch chains are also used on the Besbrook-Newry electric railway and on the Ryde Pier cars. Mr. Holroyd Smith adopted this mode of transmission on the first cars at Blackpool, in England, but he has since changed it to worm gearing, with which he is better satisfied.

CONICAL DISCS AND CHAINS.

About five years ago I had the idea that it might be advantageous to vary the speed of a car mechanically without interfering with the motor or even the supply circuit. I took out a patent for this in 1882, and applied it to the propulsion of a large street car. The motor was carried by a frame supported upon the axles by bearings and springs, to counteract the effects of vibration. By this arrangement the whole apparatus was rendered independent of the car body, and it could be easily detached. The speed pulleys consisted of conical discs, which, when placed face to face on a shaft, each pair formed between them a grooved pulley, and by shifting these discs on the shaft towards or from each other the said groove could be made wider or narrower, as desired. Two pairs of discs on different shafts were connected by means of a chain, the links of which were surrounded by wedge-shaped pieces of leather. The cross-section of this chain band was thus shaped in order to fit into the V-grooves offered by the cones. When the said discs were pressed closely together, then the band assumed a position near the circumference of the discs, but when the latter were separated, then the groove widened, the band changed its position and ran on some portion of the conical surfaces nearer the centre of the pulley. Thus the effective or acting diameter of the first motion pulley was varied at will by pressure, and the cones on the second motion shaft followed suit automatically, because the length of the band was constant, and the second pair of cones was pressed together by a strong spring. This arrangement looked very nice, but its efficiency was low; there was a great waste of power through friction, and we finally abandoned it. It worked silently, it was strong, and took up little room. The band slipped often when the car was starting or mounting an incline.

STRAPS AND PULLEYS.

Mr. Volk, of Brighton, England, employs leather link belts with great success for transmitting the power of the motor to the car axle. This railway has been in operation since August, 1883. Mr. Volk tried first, single leather belts, but they broke every day or two; then he used double belts with little better results; and some three years ago he adopted the leather link belt, which has given entire satisfaction. I have seen one of the latter which has driven a car over 50,000 miles and it was not worn out then. These belts stretch when first put on; the bearings of the countershaft are therefore made adjustable by means of a slide whereby the slack may readily be taken up. When starting the car the belts slip a little, but this is not considered a disadvantage. There are no curves on the Brighton line, and I often wondered whether this method of gearing would satisfy the terrible pull on the very sharp curves which occur on some street railways.

Mr. Van Depoele has given a high testimony in favour of link belts of a special construction after using them for a considerable time, and running them at a great velocity. Like Mr. Volk, he attaches the motor to the car body in order to give it the benefit of the existing flexibility of the car springs. Mr. Van Depoele's link belts, I understand, are made of steel, with special bearing surfaces; they have been used on a line of his construction at Windsor, in Canada; at Scranton, Pa., he employs spur gearing.

SPUR GEARING.

There exists a variety of opinions on the subject of toothed wheels in connection with electric motors, and each opinion seems based upon actual experience. I have seen spur gearing used on electric cars in Europe and in this country, and I give you freely all I know about it. The first I saw was on the Moedling line, near Vienna, in Austria. The noise created there was not very great, but there was occasionally some trouble due to the untimely deterioration of the teeth. This was especially remarked by the manager of the Frankfort Electric Railway in Germany, which is constructed on precisely the same principles, with the difference that the former runs through a country district where there is much less traffic, and the rails are laid on the tops of transverse sleepers like a steam railroad; there is less dust and mud to contend with. Between Frankfort and Offenbach, on the other hand, the rails are laid through populated streets, whereby all the disadvantages of city traffic are brought into play. The gearing of the cars on this line is very noisy, and it wears out quickly. The train of wheels consists of a pinion on the motor shaft having 17 teeth, which gears into a spur wheel of 56 teeth keyed upon a countershaft. On this countershaft is a pinion of 26 teeth, and this drives a spur wheel of 52 teeth, fastened to the car axle. The velocity ratio, therefore, is as 1 to 6·6 between the motor spindle and the driven axle The armature makes about 550 revolutions when the car travels at the rate of seven and a half miles an hour. The pinions are made of hard gunmetal, and they wear out in about a month. I have seen a number of rejected pinions, the teeth of which were ground into the shape of a fine wedge. The spur wheels are of cast steel, and they last about ten months when in continuous service. I was surprised to see these; and what with the noise, the excessive weight and other drawbacks, it made me more than ever prejudiced against such a mode of mechanical transmission on street cars. My views on this point have, however, been somewhat modified since I have been in this country. I had the privilege of being

Digitized by Google

invited to assist Mr. W. Wharton, jun., of Philadelphia, in fitting up an electric street car. There we used a set of spur gearing which was supplied by the Sprague Company. In this case the motor shaft, which runs at from 500 to 600 revolutions a minute, carries two steel pinions, one at each end of the shaft, and these pinions gear direct into two cast iron spur wheels upon the driving axle, without any intermediate wheels. The motor is partly suspended on the axle and partly on the body of the car. We have run several hundred miles with this car under all conditions of loads, gradients, and weather, on some of the roughest tracts in Philadelphia, but up to this moment not a single hitch has occurred. The gearing is practically noiseless, it is efficient and strong, and I see comparatively little indication of wear. The teeth are beautifully shaped, therefore somewhat expensive, but if they last long enough, and if they do not rattle when partially worn, this expense can be ignored. This car contains, besides its usual weight, about 3,200lb. of storage batteries; it has to mount grades of 5 per cent., and run on curves of 35ft. and even 25ft. radius, which means very hard work.

(To be concluded.)

REPORT OF THE BRITISH ASSOCIATION COMMITTEE ON STANDARDS OF LIGHT.

The committee has been anxious during the past year to carry out comparative experiments on the various standards of light hitherto proposed, but has been prevented by want of funds from doing much. Prof. W. G. Adams, however, has presented a report to the committee on preliminary experiments made by him, and the committee is fully convinced that if provided with funds they will be able during the next year to complete experiments which will lead to recommendations which, if adopted, would place the question of standards on a satisfactory footing.

ON SOME POINTS IN ELECTROLYSIS AND ELECTRO-CONVECTION.*

BY PROF. G. WIEDEMANN.

I must congratulate the British Association on the reports of the Committee on Electrolysis, and specially that Prof. Oliver Lodge has directed the course of its investigation, for it could not have been entrusted to abler hands.

Some time ago I read a very interesting report which Prof. Armstrong communicated at the last meeting of the British Association, and the hypotheses he has advanced on the subject of electrolysis. There is a great deal that is hypothetical in these things. Allow me, therefore, to give expression to some aphoristical suggestions about some points more accessible to observation which I think ought first to be discussed.

I. The first question is, What is an electrolyte? What compounds are electrolytes? What are the ions of the electrolytes? Now, one generally says that electrolytes are salts, that they are binary compounds. But what is a binary compound? It is a compound decomposed by a current into two different compounds or elements; and when you say that electrolytes are salts you may as well say salts are electrolytes. Therefore it is very difficult to give a definition, and, even if we assume the general though not clearly defined idea of salts, we get into great difficulties. For instance, Prof. Hittorf has said that electrolytes are compounds which by double affinity may exchange their elements with those of another recognised electrolyte. But that is not generally true. First, we have certain bodies which seem not to be decomposed by the current, though they exchange their elements with those of other compounds which are electrolytes. Take, for instance, anhydrous hydrochloric acid. It does not conduct. Nevertheless, as Dr. Gore has shown, if you put it upon carbonate of lime, the carbonic acid is chased away and chloride of calcium is formed. And, to give another example, the chloride of propyle is a non-conductor; nevertheless, when you treat it with bromide or iodide of silver the chloride gets changed into bromide or iodide.

With just reason you may object that this is no proof, for perhaps the chloride of propyle is only a very bad conductor; therefore the current does not pass in a sensible way, and we cannot observe the decomposition. In this respect we may refer to the researches of Mr. Bleekrode, in Holland, and Mr. Bartoli, in Italy.

* Read before the joint sitting of Sections A and B at the British Association Meeting, Manchester, 1887.

But, on the other side, we find well-known electrolytes exchanging their ions with elements of other compounds which, without any doubt, are not their ions. So, for instance, chlor-acetic acid ($CH_2ClCOOH$), or the ethylic ether of this acid, and iodide of potassium exchange between each other the chlorine and iodine, though assuredly the ions of chlor-acetic acid are not Cl and CH_2COOH, but CH_2ClCOO and H.

Another difficulty is offered by the alloys. A former observation of Mr. Gérardin that amalgams of sodium grow brittle on one or the other electrode was refuted in my laboratory about eleven years ago by Dr. Obach.* His researches were made with the greatest care, and extended over different alloys, even those which contained definite equivalents of their elements, and which from their other properties seemed to be definite chemical compounds. But no decomposition was observed. Somewhat later Mr. Haga, in Holland, made analogous experiments with the same result. It would give me great satisfaction if Prof. Austen should confirm these observations.

After these experiences we must confess that as yet we do not know the general definition of an electrolyte and of its ions.

II. There is another open question, whether water takes part in the electrolysis of a dissolved electrolyte. You have heard from Dr. Lodge that the answer to this question is generally negative. On the other hand, Prof. F. Kohlrausch,† in his very remarkable paper on the conduction of some electrolytes in very diluted solutions, came to the opinion that in these solutions water is also decomposed. It would be very desirable that further researches should be made on this subject.

III. Let us neglect the surely very insignificant decomposition of water, and assume that it plays only a secondary part in the electrolysis of solutions. Then we may enter upon the consideration of their electrical resistance.

It is now generally admitted, as I detailed so long ago as the year 1858,‡ that the electrical resistance of a solution is determined by the mechanical resistance (friction) the bodies set free by the current encounter in the liquid, by which means the lost motion is transformed into a quantity of heat proportionate to the electrical resistance. In the same year I *compared* this friction with the viscosity of the liquid. I believe this has been often misunderstood, for I find it stated in some memoirs that I should have said the viscosity of a liquid *represents directly* its resistance. On the contrary, and specially in a paper of the year 1856, I have shown that the friction corresponding to viscosity is different from the friction in the electrolysis of solutions.

In the year 1870, in the second edition of my "Treatise on Galvanism," Vol. I., p. 432, I have further detailed the three points separately to be considered in this electrolysis, viz., 1st, the friction of the ions in the liquid; 2nd, the friction of the dissolved electrolyte in the liquid; 3rd, the friction of the whole solution in the vessel, the electrical endosmose. I am happy to state that on these points I agree with my excellent friend, Prof. Quincke, who independently and nearly contemporaneously evolved the same ideas.

We will omit the electrical endosmose, which can be eliminated, and deal only with the first two points.

The friction of the ions alone has been further treated by Prof. F. Kohlrausch, and with the help of the admirable experiments of Prof. Hittorf on the migration of ions, and his own most elaborate researches on conductivity, he has shown that, independently from the compound decomposed, each ion has its own constant velocity in the same solvent. The discrepancies which were observed in stronger solutions disappear, as Prof. F. Kohlrausch has stated, in most dilute solutions, where the friction on the water is almost the only thing to be considered.

But with regard to very dilute solutions, I believe we encounter some great difficulties, at least for certain compounds.

1st. There may be double decomposition of the dissolved electrolyte with the impurities of the solvent. In very diluted aqueous solutions these impurities, even in the cleanest water, conduct better than the dissolved solid. It may be that this double decomposition may have no great influence on the results.

2nd. A greater influence can be exerted by dissociation of the salts. It is known that solutions of sulphate of copper, &c., are acid, that a solution of chloride of magnesia when boiled emits vapours of hydrochloric acid, that chloride and other salts of ammonia are dissociated in their aqueous solutions, &c. The increase of the dissolving water must increase these dissociations.

3rd. In many cases we are not sure if the dissolved electrolyte is to be regarded as free from water or as a hydrate (in alcoholic solutions as an alcoholate). By the researches of Graham, Rüdorff, and others, we know that such hydrates exist in the solutions. Now Prof. F. Kohlrausch, in his already quoted memoir (p. 201), has found no influence of the formation of hydrates. On the contrary,

Prof. Eilhard Wiedemann, of Erlangen, has observed that there is a definite influence. You know that chloride of copper in very concentrated solutions is green, in more diluted, blue. This change of colour is, without doubt, produced by the combination of the salt with the water. In the same manner diluted blue solutions grow green by a rise of temperature. Now the electrical conductivity of solutions of this salt at each rise of temperature of 5deg.C. augments nearly by the same amount up to 60deg.C. ; but above 60deg.C. the change of conductivity for 5deg. falls off in a remarkable manner. The same is to be observed when the solution contains free hydrochloric acid. A solution of chloride of sodium—which salt forms no hydrates at not too low temperatures—shows no such irregularities. Its conductivity rises faster than the temperature up to higher temperatures. These experiments shall be further followed up. Without doubt the number of the salt molecules combined with hydratic water must increase with the dilution.

It seems to me at present impossible to avoid these disturbing circumstances, which nevertheless should be put into consideration. Therefore we should not content ourselves with the determination of the conductivities of very diluted solutions, by which certain complications are avoided, but new ones may be introduced. Only by the study of gradually changing concentrations of the solutions at different temperatures, and comparing their electrical behaviour with their other physical properties, may we get an insight into these different conditions.

The formation of hydrates of the salts and their dissociation must also be understood before we can enter with any hope of success into further discussion of the highly interesting and important question, principally treated by Dr. Svante Arrhenius, whether the eventual formation of complex molecules and their dissociation by further dilution may have an influence on the number of molecules decomposed by the current, and on the resistance of the solution.

For the same reason the question how much of the resistance may be due to the friction between the undecomposed salt and the dissolving medium, which have a certain difference of electrical potential between each other, and therefore are transported in opposite directions by the current, must be postponed for further researches.

IV. Another point which merits ample consideration and serious criticism is the supposed relation between molecular conductivity and chemical composition. The conductivities of dissolved salts give no such immediate relation ; nor is any to be expected, since they are dependent upon the sum of the velocities of the two ions. The same may be said about the conductivities of worse conductors, the organic compounds, &c.

Great care should be taken in these researches to employ only chemically pure substances. After the interesting observations of Mr. Ramsay about the boiling points and vapour tensions of organic compounds, it seems not to be sufficient to content ourselves with getting them from even the best chemical works and testing them by their boiling points, the more so as the conductivities of bad conductors may be considerably changed by the addition of very small quantities of other substances.

By a long series of careful experiments Prof. Ostwald has tried to find between the mono, bi, and tri, valency of the acids, and their molecular conductivities in very dilute solutions, a relation which should be in inverse ratio to the valency ($100 : 50 : 33\frac{1}{3}$) ; but it seems not to follow from his researches ; as, in solutions of different acids containing only one molecular weight in grammes in 1,000 litres of water, the numbers for the molecular conductivities vary for the monovalent acids between 112·5 (HBr) and 12·65 (isobutylic acid), for the bivalent between 113·4 (H_2SO_4) and 16·91 (succinic acid). The different changes of the molecular conductivities with increasing dilution (from 100 to 1,000 litres of water for H_2SO_4 from 102·7 to 113·4, for isobutyric acid from 4·41 to 12·65, &c.) cannot encourage to a very far extended extrapolation which might conduct to the above law.

Therefore till now we must content ourselves with some minor regularities.

One of these has been observed in the laboratory of Prof. Eilhard Wiedemann by Dr. Hartwig. According to his experiments the conductivities of the acids of the fatty series attain with rising concentration their maximum the earlier the more carbon they contain, and the later the more carbon the dissolving medium (water, methylic, ethylic, amylic, alcohol) contains.

V. Also the attempt to measure the chemical strength of the acids by their molecular resistances seems to me to depend upon an erroneous conception. Already in my "Galvanism" I have mentioned that the electrical resistance offers no measure for the so-called "force of decomposition," and therefore, also, not for the chemical affinity. May we assume the former view, that the ions of a compound are directly separated by the current, or according to the now generally received theory of M. Clausius, that their motion is directed, or accelerated by it in a certain direction ; after its interruption the electrolysed solution between the electrodes and far from them is quite unchanged. The work done by the current in separating the ions or changing their motion is totally regained by their recombination or their return to their former state.

The chemical affinity, or, more rightly, the heat of chemical combination, is measured by the electromotive force ; and I believe that the law of Sir William Thomson, that the electromotive force of a cell is equivalent to the heat evolved in it, is true, if only we distinguish between the true primary chemical processes, which alone determine the electromotive force, and the secondary ones. For instance, in the magnesium cells we must calculate amongst the primary processes the formation of a highly negative suboxide of magnesium, in the cells with two liquids we must consider that their ions at their plane of separation appear and combine with each other in single atoms, while we measure directly their heat of combination when bound together into molecules, &c. In my "Treatise on Electricity," Vol. II., p. 892, I have, though but in a very few words, indicated some of these circumstances, which may explain the apparent objections to the law of Sir William Thomson. But these considerations would lead us too far from our proper subject.

VI. More intimate appear the relations between electrical resistance and the time for the formation of chemical compounds. In fact, this time depends (1st) on the affinity of the elements entering into combination or being exchanged between two compounds ; and (2nd) on the mechanical resistance which they find, while approaching each other, and which mostly has been totally neglected in these questions. Both conditions must find their expression as well in the modern theory of atomistic and molecular motion as in the older one. The first of these conditions does not enter in the consideration of electrical resistance, the second does, so that even when in both cases the processes were quite the same, we could not expect a proportionality between the time of combination and electrical resistance. Nevertheless, the experiments of Prof. Ostwald,* though treating very heterogeneous processes, indicate that between the time for the inversion of cane sugar, the catalysis of acetate of methyl by different acids, and their electrical resistances, there may be a certain relation ; though the numbers, as may be expected, show considerable differences : (if we put these constants for HCl equal to 100, they are for some other acids 65·1 and 73·4, 79·9 and 91, 74·6 and 104).

It seems to be very difficult, even if possible, to study both conditions which determine the velocity of the formation of compounds separately, and then compare only the resistance to their formation with the resistance opposed to their ions during the passage of the current.

So we see that a great deal of work has yet to be done in electrolysis, and I hope that the impulse given by the Committee of the British Association will mightily contribute to advance our knowledge in this most complicated and difficult problem.

DISCUSSION.

Prof. QUINCKE: I can endorse the views of Prof. Wiedemann about the influence of the secondary decomposition in the solution of solids in different liquids, and I think it very difficult to distinguish between the primary and secondary actions. I think we shall have a clearer view as to the decomposition of electrolytes if we employ other physical methods to trace very small quantities of the solids or of the ions of the solids—and to decide if we have secondary or primary decomposition in electrolysis. For instance, I think that the new researches of Prof. Lodge, on the migration of the ions in thermometric tubes and in jellies, will bring out new facts so as to enable us to understand electrolysis and how the chemical compounds are decomposed in the different solutions ; and I hope to learn something also from these different numbers (referring to Mr. Fitzpatrick's diagrams on the wall) of the decomposition of different solutions of the same solid in different liquids.

Prof. ROWLAND, having been invited to speak, said that this was a subject which he had not studied, and therefore he could not make any remarks on such elaborate investigations.

UNDERGROUND TELEPHONE WIRES AT BROOKLYN.

BY W. E. SARGENT.

In my remarks on underground work last year the style of our creosoted wooden conduit was fully described. In the latter part of December, 1886, in consequence of the passage of an amendment to the existing ordinance by the board of aldermen, the commissioner of city works refused to issue permits for opening the streets. For this reason our underground work has been at a standstill. We had submitted plans for 1887 for six miles of creosoted wooden conduit, which were approved by the subway commissioners, but, for various reasons, an application to the courts for

* Ostwald, *Journ. für praktische Chemie*, N.F. XXX., pp. 93—225 1883.

Digitized by Google

a *mandamus* has been delayed until now, and a decision is expected in the next few days. The Dorsett conduit, five miles in all, connecting Brooklyn and Williamsburg, when completed, proved to be very defective. The faults in it are due to several causes, but chiefly to carelessness in laying it in the ditch and making the joints. After a great deal of work, occupying all this year, the ducts are now reported ready for occupancy. The Dorsett material is very rough, and at the joints it squeezed through the cracks, making projections that were broken off in the process of clearing out, and brushes had to be run through to clear these pieces out. Even now the ducts are so very rough that a lead cable is badly scratched in hauling in. It was claimed this material was gas-tight, water-tight, and even mud-tight, but all of these things have been found in the ducts and manholes. The only explosion of gas we have had in Brooklyn was in a Dorsett manhole. Recently the elevated railroad people exposed about eight feet of the first creosoted wooden conduit we laid three years ago. There is not the slightest decay externally, and the ducts inside are clean and dry, the friction rollers running as smoothly as when first laid. Looking backwards, we feel that, had we to do the work over again, we should enlarge the ducts to 3 × 3in. inside on double or treble their number, because we now see that with increased diameter necessary in cables and the use of double conductors, our space will soon be exhausted. We had expected to be able to lay six miles of conduit this year, which would make a total of twenty miles. This work was prevented by the conflict of authority between the subway commissioners and the board of aldermen. No change has been made in our plans for distributing, and we expect to do this from terminal poles and housetop fixtures. The Brooks cables, covered with pure lead, have now been in service three years. The corrosion of the lead pipe noted last year is still going on, with indications that it will take several years more to reach the insulated wires. The Western Electric cables, lead with a small percentage of tin, placed in the same conduit at the same time, show only a thin hard white scale, with no indications that it is increasing. The New York and New Jersey cables, covered with lead and tin, have been in the conduit about nine months, and they show no corrosion beyond a thin scale. I think we may assume that a composition of lead and tin resists the action of the gases in the underground conduits. We now have eighteen cables, aggregating 1,700 conductors, leading out underground from our Brooklyn central office—939 of these conductors are in actual service; six cables, aggregating 500 wires, leading out from the Bedford office—175 of these conductors are in actual service. We have, all told, sixteen miles of cables underground; 1,500 miles of conductors, 900 miles of which are in actual service. The cables leading out from Brooklyn central office range from 900ft. to 7,180ft.; in Bedford from 460ft. to 2,250ft. The first cables furnished by the Western Electric Company, 100 wires mixed indiscriminately, have been in service since November, 1884, and have given satisfactory service, with one intermission on account of defective terminals. This difficulty seems to have been solved by their last device for that purpose, and no serious decline in the insulation has occurred for the past two years. The wire used in all our present cables is ·035in. to ·038in. diameter, with insulation ·075in. to ·088in. Realising that metallic circuits will be necessary in underground work, all our cables were ordered twisted in pairs or groups of four. Through a misunderstanding, a portion of the cables were furnished indiscriminately. We now have cables with the conductors related to each other in three different ways. It was found at once that the cross talk between two of a pair, or two of four, was too great for satisfactory service. There is no cross talk between the pairs or the groups of four. One cable of 7,160ft., 100 wires twisted indiscriminately of the Western Electric manufacture, has some cross talk, but not enough to prevent its use, and 84 of the 100 wires are in active service. The insulation of the cable varies from 650 to 450 megohms in summer, and the capacity is ·227 microfarad per mile. The next in length was made by the New York and New Jersey Telephone Company, 6,660ft. with 100 wires twisted in pairs. The cross talk between pairs was so bad that we were compelled at once to take measures to remedy it. The joints were opened and the pairs broken up at all the manholes at intervals of about 800ft. The effect of this work was to reduce the cross talk between pairs and distribute it among all the wires. It may be expected, of course, that more frequent transpositions would make the cable just as good as the Western Electric. This is not practical, and we shall restore the wires to their original relations, grounding the twin wire until the metallic circuit era arrives. The insulation of this cable ranges from 54 to 29 megohms per mile, and the capacity is ·3 microfarad per mile. Thirty subscribers are working through it. The shorter cables give similar results, diminishing proportionately to the length. To connect our Brooklyn central with branches at Bedford and Williamsburg will require two and a-half to three miles of cable, and we believe if we followed the Western Electric type there would be enough cross talk to make them valueless, or if we ground the twin wire in the New York and New Jersey type we believe there will be retardation enough to make serious trouble. We have therefore decided to make our long trunk lines of copper ·050 in diam. and insulation ·125 in diam. This reduces the copper resistance nearly one-half, and increases the thickness of the insulation. Sixty wires of this size may be put in 1⅛in. core, making a cable with an outside diameter of 1½in. We are restricted to this size by the 2in. holes in the Dorsett conduit. The insulation of the Western Electric cables quoted shows there has been no reduction since the last terminals were put in. The N. Y. and N. J. cables do show loss of insulation, but we attribute this to the joints and terminals, our men lacking skill and experience. Time will prove this, and, other things being equal, we believe both cables will give good results. A 25-wire okonite cable was drawn into the creosoted wood on ducts in the summer, when it was moved to make room for more wires. There is no sign of deterioration or decay in the rubber, and the insulation is 150 megohms per mile in water since it was taken out of the conduit.

It is generally believed that rubber cables will be damaged or destroyed by lying in creosoted wooden ducts, unless protected by lead. It would be interesting to make further trials to demonstrate whether this be so. For terminal wires leading from the conduit to the building some form of rubber or gutta percha wire is the most convenient.

UNDERGROUND AND AERIAL TELEPHONE CABLES AT CHICAGO.

BY E. B. SUNNY.

A mile of Patterson cables has been put down in West Madison-street, in Chicago, made up of one 150-wire cable and cables of from 25 to 125 conductors, containing in all about 200 miles of wire. No. 18 American gauge was used, and the insulation and capacity tests are very satisfactory. These cables were put down to abandon a pole line of ninety wires built about six years ago. Notwithstanding the fact that the wires on the route were badly decayed, and contained many defective connections, and that the cables were of the best manufacture, the wires on the pole route talked about 25 per cent. better than those in the cables. The cross talk is only noticeable at times, and is not heavy. These cables are laid in a box of creosoted wood and covered with ¼in. tarred sheet iron. The box is just big enough to take the cable, and no filling of any kind is used. A gang of twenty men put this cable down at a rate of 500ft. per day, finishing up everything excepting the permanent restoration of the pavement. Eleven hundred feet of conduit has been built to carry the cables from the present central office to the new building. The construction includes the use of wrought-iron pipe 2½in. inside diameter, free from burs and presenting a smooth surface to the cables. The pipes, sixteen of them in all, are spread apart, and the interstices filled with concrete. We are putting 18-gauge 200-conductor cables into the pipes, and find that they work smoothly, and that a gang of six men can put in four pieces of cable 400ft. each per day. The underground cables put down two years ago are giving satisfaction. Recent tests on some of them show an insulation ranging from five to fifteen megohms. One cable put down by the Standard Company two years ago indicated a very low insulation on the regular test. We opened the street in two or three places, and finally located the fault in a splice. No abrasion of the lead pipe could be noticed, nor was there any superficial evidence of a fault. A piece, including the splice, was cut out, and another piece of cable put in. The piece cut out was laid on a board, and shortly it was noticed that water was coming out of the splice through a blow hole the size of a pin in the solder. There was perhaps half a pint of water in the sleeve. It took two years for the fault to develop. In another instance a standard cable was cut into by plumbers some time last November. In June the insulation was found to be low, and when the fault was located it was discovered that the water had gone into the core through a bad cut in the lead, and had worked back 40ft., requiring new cable to that extent. We have several cables, chiefly aerial, that are defective, and are being looked up. It requires the constant attention of a galvanometer corps to keep them in good shape. By means of semi-annual tests defects have been discovered and removed before they had time to affect the service. The trouble from low insulation at the terminals is being overcome by filling the terminals with paraffin wax, or some other insulator, and keeping the terminals well protected from moisture. The trouble outside of the terminals on air cables is made up of cuts in the lead by hooks cutting through, bullet holes, and careless workmen. The following test, recently made, may be of interest:—Two wires were selected which ran together, through nine cables of seven different styles, a distance of 4·4 miles. The cables are Patterson aerial and underground and standard aerial and underground, and contain from 50 to 150 wires, each ranging from 18 to 26 gauge. The resistance measures 444 ohms. The first test was made on a day of alternate sunshine and rain, when everything was damp. There was abso-

Digitized by Google

lutely no cross talk from one wire to the other, and conversation could be carried on freely and without any more effort than on an air line. The introduction of an annunciator drop into the circuit made no difference. A test for insulation showed 400,000 ohms for the distance and a static capacity of 1·4 microfarad. A week later the same wires were used in the same manner with less satisfactory results. The weather was dry and warm. It was found that counting on one could be distinctly followed on the other, and *vice versâ*. The cross talk from the other wires was very noticeable, but not of sufficient volume to disturb the user. Conversation at a distance of eight inches from a fairly adjusted transmitter was indistinct and muffled. With the lips close to the transmitter, and by speaking in the usual tone of voice, the results were fairly satisfactory. This was particularly true when an air line of one and a-half mile was added. The measurements made after the test showed the insulation to be 4 megohms for the distance, against ·4 of a megohm on the previous test, and 1·05 microfarad capacity against 1·4. By opening one of the wires at both ends, so that all connection with the earth was removed, conversation could be freely carried on between three parties who were looped in. The first one was 5,000ft. from the open end of the cable, and the other 12,000ft. The only difference noted by the intermediate parties in the working of the wires with the ends open was that the cross talk was much heavier than with the grounds on. The second test indicates conclusively that we have used up all of our margin and that a slight addition to the length of the cables will make the connection of no commercial value. In fact, in ordinary dry, clear weather, conversation is only carried on by frequent repetitions and considerable discomfort. The nine cables included in this test are all in good condition, and with the exception of a few pieces of air cable, are new. On the above circuit there are sixteen terminals in use, but in all cases, except in exchange offices, the cable wires of one cable were connected with those of another at the terminals with kerite or okonite wire, so that the insulation was good at these points. The experience of four years has proved the fallacy of the practice of requiring the manufacturers to furnish a cable showing an insulation of from 300 to 800 megohms per mile. While this insulation can be secured immediately upon the completion of a cable, it is utterly impossible to maintain it. Nor is it desirable to maintain it, for the reason that cross talk is greater on a cable with a "fancy" insulation than in one of a megohm. Subscribers always complain of cross talk when their wires are put into a new cable, but after a few months we hear no more about it. This is not so much because they have become accustomed to the cross talk as it is that with the lowering of the insulation the cross talk is decreased. A better specification would be one megohm per mile and not more than five, and a guarantee from the manufacturer that this insulation will hold up for ten years. Such an insulation exceeds anything that we are able to get on air lines. In a recent test nine wires showed each an insulation of 5·3 megohms. Rain began to fall, and it ten minutes the insulation had fallen off to 3·2, and no doubt went lower. This illustrates the extreme sensitiveness of a high insulation to moisture, and indicates clearly that where there is a large number of cables in use the conditions are constantly varying, and nothing like uniformity in the working of the wires can be expected or secured.

ON JOINING LEAD-COVERED CABLES.

BY MR. PATTERSON.

The only thing to look out for in making a joint in a lead-covered cable is to keep out moisture. The ends of the cable, after the cable is made, should always be sorted out. Then after the cable is drawn into a conduit, the end of the pipe is cut off and the pipe removed from the core for a distance back corresponding to the size of the cable. For a 100-wire cable we would want to strip about 18 or 24 inches on each end. On the new style of cables arranged for metallic circuit each pair of conductors are twisted together and served with a single splint of cotton. The serving around the two wires will hold them in place until the man who is doing the splicing deliberately removes it. One is covered with white cotton and one with red and white—some colour that can be easily distinguished. The two wires are brought together, and the way we generally make a splice, and the best way, I think, is to strip the wires for an inch and a-half, bring them together, and instead of making a long splice, bend them up and then twist the ends together. That will leave the wire running through and the two ends twisted together standing at right angles to it. A cotton sleeve is drawn over it. This sleeve is like the outer braiding of office wire. After all the wires are spliced in that way they should receive a bath in very hot paraffin, poured on while they are laid out loosely to remove moisture, which they may gather from the atmosphere and from the hands of the men. Then the core should be covered and brought down to a compact size, that the lead sleeve will slip back over it. After that sleeve is on it should receive another paraffin bath. After the work is all done it is well to take a torch or something of the kind and pass it along underneath the cable and melt the insulation for a distance of one or two feet each side, so as to put on a pressure and test the joints; if there is any flaw it will show itself by the paraffin oozing when the pressure is put on. Occasionally, in underground work, it is not convenient to make a sleeved pipe. In that case we turn both ends of the cable up and bring them out through the top and have a brass casting in the form of an inverted Y. The two branches of the Y are of such size that the cable pipe will slip into them, and the main outlet is large enough to make the splice. The wires are brought up through it and spliced together, and the opening covered by a cap. After the work is done, that Y is dropped down into the hole and lifted. That removes the necessity of doing the work in the manhole. It is lifted up to the level of the street, and the man sits on the edge with his feet inside and works on it.

COMPANIES' MEETINGS & REPORTS.

The Eastern Extension, Australasia, and China Telegraph Company (Limited).

The twenty-eighth ordinary general meeting of this Company was held on Wednesday, 26th October, at Winchester House, 50, Old Broad-street, Mr. John Pender in the chair.

The SECRETARY (Mr. F. E. Hesse) read the notice convening the meeting and the minutes of the previous meeting, which were confirmed and signed by the Chairman as correct. The report and accounts were taken as read.

The CHAIRMAN: I will, with your permission, now give you a few details as to the last half year's working. The gross receipts for the half year were £219,201, against £224,843 for the corresponding period of 1886, or a decrease of £5,642. This result, however, is not unsatisfactory having regard to the fact that in the corresponding period the reduced tariffs had not come into operation. The reductions agreed to at Berlin were, however, based on the figures of 1884 and 1885, which were the best years we have ever had, and although we shall this year carry a larger number of words than in 1884, we shall have only made up about £18,000 of the loss of £50,000 per annum, which was estimated from the reduced tariffs, leaving over £30,000 still to be recouped. As the traffic is increasing this loss will doubtless be made up in course of time; but our experience shows that the traffic does not respond so readily as the advocates of low tariffs would have us believe. The expenses for the half year were £76,241, against £81,775 for the corresponding period of 1886, showing a decrease of £5,534, which is due to our having disposed of the "Agnes," and having consequently had during the past half year only two maintenance ships, against three in the corresponding period of 1886. The net revenue for the half year was £97,662, against £97,480 for the corresponding period of 1886, showing an increase of £182. One quarterly interim dividend of 1½ per cent. has been paid during the half year, and another of like amount was distributed on the 15th inst., leaving £35,162 to be carried forward to the current half year, at the end of which the question of bonus distribution will be dealt with. I have during the last week, since the report was issued, received six letters from shareholders on the subject of the printed accounts, three of them having reference to the non-payment of a bonus for the half year. It was, however, always understood that any bonus that might be declared should be paid at the end of the year after having ascertained the result of the year's operations. We were, however, at one time urged by some of our shareholders—in 1884 or 1885 I think it was—to make the distribution half-yearly, which we did for several years, but after the reduction that we had to submit to at Berlin we thought it was more desirable to postpone it till the end of the year. No doubt at the end of the current year we shall be able to pay a portion of it at all events, and thus redeem our promise as we did in previous years. There have been no serious interruptions to our system during the past half year, although numerous repairs have been effected, and all the sections, excepting the Tonquin-Hong Kong cable, which is at present undergoing repair, are now in good working order. Since the close of the half year under review a further portion of the Singapore-Saigon section, which is the only main cable unduplicated, has been renewed with brass-ribboned cable to the length of 174 nautical miles, leaving about 150 nautical miles to be renewed. This will, in all probability, be completed during the current half year, in which case the cost of the operation will be shown in the next published accounts.

This question of the renewal of cables, and the damage effected by the teredo is a very important one. We had for many years constant cause for repairs by the action of that insect, but we set our brains to work, and the result was that we hit upon a plan which has greatly obviated the difficulty, by using brass-ribboned cable. The following statistics will show the value of brass-ribboned cables in teredo-infested waters:—Before the Singapore-Batavia cable was renewed in 1881 no less than 194 faults were removed in 11 years, or on an average 18 a year; whereas, during the last six years only four breaks have occurred, and these have been entirely due to ships' anchors. On the Banjoewangie-Darwin cable 67 faults occurred before it was partially renewed in 1884, since which time not one fault has occurred in the brass-ribboned portion. The same remark applies to the Singapore-Saigon cable, which was partially renewed in 1885, although forty-nine faults had previously occurred. Consequently our experience, extending over a period of nearly seven years, clearly shows that

Digitized by Google

the brass-ribboned cable has successfully resisted the attacks of the teredo, from which we sustained so much damage until we adopted this valuable form of protection. The Company's new shore cable establishment at Singapore, in place of the hulk, "Southern Ocean," has been completed, and the tanks and machinery from the latter were transferred to the shore establishment before the hulk was sold by public auction.

At the last meeting I went fully into the details of our relations with the Australian colonies and New Zealand, and have now only to state that during the last six months, since the return of the delegates to their respective homes and Governments, nothing has been done. At the end of next month, I believe, there is to be a conference at Adelaide to consider the question of cheaper postal rates and lower telegraph rates between the mother country and the colonies; and until the Directors hear of the decision arrived at their policy will be to leave things alone. Since the last meeting of the Company a fresh Parliament has been elected in New Zealand, and the Government from whom the Company had differed were out of power. As soon as their successors have had a little time to settle down the Directors will resume the correspondence, with, I hope, a fair prospect of success. The Company have been in negotiation with the Chinese Government during the half year, and have tried to show that Government that submarine telegraphs were a great necessity for China, and the Chinese Government endeavoured to prove that land lines would beat the submarine system. The result has been that an understanding has been come to by which both interests will be properly protected. The points of the agreement have been settled, and it simply awaits the approval of the Chinese Foreign Office; and when that matter is settled I hope that for the next sixteen years we shall be able to look at the growth in the China trade without any fear of undue competition. I may mention that nearly the whole of our system is duplicated—I might almost say, triplicated—so that we are in every way in an efficient condition for the conduct of our business. Our relations with the Imperial and Colonial Governments are of the most friendly nature. The other day the Imperial Government laid down a cable to Port Hamilton, which they afterwards found they did not require, and we took the opportunity to take it off their hands at such a price as would enable us to utilise it with advantage. I think that I have gone over all the points that it is necessary to call your attention to, and I will finish by saying that our relations with all foreign Governments are very satisfactory and our revenue is increasing, and I hope by the time we meet you six months hence we shall be able to show that there has been considerable progress for the half year, and that we shall be able to resume the payment of the bonus. I will conclude by formally moving the adoption of the report and accounts.

The Most Hon. the Marquis of TWEEDDALE seconded the motion, which was carried unanimously.

A vote of thanks was afterwards passed to the Chairman and Directors, and the proceedings terminated.

Hammond Electric Light and Power Supply Company (Limited) (in Liquidation).

An extraordinary general meeting of this Company was held at Winchester House, Old Broad-street, yesterday (Thursday), under the presidency of Mr. William Theobald (the liquidator).

The SOLICITOR having read the notice convening the meeting,

The CHAIRMAN, in the course of his remarks, said: I feel that before I go to the report I should refer to the circular issued in April last, stating that we should probably call a meeting in the following June. Soon after that circular was issued I found, on looking into the matters outstanding, that they were so few and of such little value that if I deferred calling the shareholders together for a little while, I should be able to place before you the final accounts, and that I am able to do to-day. I have the pleasure of presenting the following report upon my duties as liquidator, which I venture to think will reveal a more satisfactory result than was at one time anticipated. On the 10th of June, 1885, I was appointed by the Chancery Division of the High Court of Justice provisional liquidator of your Company, with power to carry on the business, so far as was necessary for carrying out and completing existing contracts, and to pay wages and other charges. On the seventeenth day of the same month, at an extraordinary general meeting of the members it was resolved that the company should be wound up voluntarily, and I was appointed liquidator. The following shareholders were at the same time appointed a consulting and advising committee, viz.:—Messrs. E. H. Brown, A. M'Alister, and F. W. Reynolds. Immediately on taking possession of the assets and undertakings of the Company, including as they did important uncompleted contracts, it became apparent that many of them were of a very special character, their advantageous realisation demanding personal and most careful consideration, and I have to acknowledge the valuable assistance which was afforded me at this time by the advising committee. Valuable assistance was also rendered from time to time throughout the proceedings by Mr. Robert Hammond, which has been of substantial service to the liquidation. The peculiar nature of the difficulties attending the realisation of some of the assets may be best exhibited by a few examples [which he proceeded to give]. A lighting station at Brighton had been worked for some time, but was in a very incomplete state, and under the conditions of the lease certain of the engines used for driving the dynamos had to be removed. Although there seemed every probability that by expenditure of additional capital the lighting station might be placed on a profitable basis, it was doubtful if at that time it was paying expenses. A contract for management for a term of years had been entered into with the Eastbourne Electric Light Company (Limited), under which the Hammond Company were to bear all losses or take the profits, if any, on the working; they were also to provide the requisite capital for extension purposes, and to receive payment in debentures of the Eastbourne Company. A similar contract had also been entered into with the Hastings and St. Leonards-on-Sea Electric Light Company (Limited). Under the two last-mentioned contracts the Hammond Company had become entitled to debentures of the Eastbourne Company for about £7,050, and of the Hastings and St. Leonards Company for about £3,300. In the case of the Eastbourne Company the debentures, jointly with others to the extent of £500, formed a first charge upon the assets of the Company; but in the case of the Hastings Company the debentures only ranked after a charge for £4,000 given to the bankers. Neither of the above companies were paying expenses; and after careful consideration it was decided to risk the refusal of supplies to the Hastings Company (fortunately without causing a stoppage of their business), but to carry on the Eastbourne contract for a time in the hope of obtaining a purchaser for the debentures, who would also undertake to perform the contract. With this object in view the liquidator made overtures to the Anglo-American Brush, the Edison and Swan, and other electric light companies. Protracted negotiations and correspondence also were carried on with the representatives of all the various interests concerned, but without satisfactory result; and after long and tedious efforts to sell by private treaty it was determined to offer for sale by public tender not only the Brighton Lighting Station, the Hammond Company's interests in the Hastings and St. Leonards-on-Sea Electric Light Company, and the Eastbourne Electric Light Company, but also what remained of the hiring installations in other parts of the country. Advantage was taken of the issue of a circular by the Consulting Committee on the 16th September, 1885, to forward a copy of the advertisement of this sale to every shareholder on the register. Offers were received for each of the properties mentioned, some of which were immediately accepted, but in other instances improved prices were obtained by subsequent negotiations. The issue of the tender forms and the acceptance of each offer were made with the approval and under the direction of the Court. I found it impossible to arrange any scheme for the reconstruction of the Company; and as inquiries are still occasionally made on the subject, I cannot do better than quote from the circular of the committee above referred to, in which they say:—"Since you appointed us to confer with your liquidator, we have carefully considered the possibility of a resuscitation of your Company, and we regret that we are unable to recommend such a course. The large amount of liabilities and claims, about £20,000, and the peculiar nature of the assets, would necessitate an immediate subscription of considerable capital, which we do not feel justified in asking the shareholders to find." They added—"We fear the prospect of any return being made to the shareholders is extremely doubtful." Since issuing this circular in September, 1885, the committee have taken no part in the management of the liquidation, feeling that the shareholders were not likely to obtain any benefit from their labours, and having at the meeting convened by the above circular resigned their position. Another of the undertakings in connection with, and, in fact, forming part of the Hammond Company, which at one time seemed likely to involve many troublesome claims for uncompleted contracts, was the Electrical College, in Red Lion-square. Having explained the steps taken in this matter, he added:—All the claims from the parents and guardians of the students, which at one time seemed inevitable, were avoided. Not one claim was sustained, and I believe general satisfaction was given. In conducting the liquidation it was often difficult to decide how far it was advisable to carry out contracts for work on hand and hiring contracts, and whether less loss would be incurred by breach of the contract than by completing it. The labour of realising the estate and in settling the claims has been much heavier than was at first anticipated. It is a source of pleasure to me, therefore, to be able to report that, whereas at one time it seemed doubtful if even the creditors would be paid in full, I am able to report to-day that they have all been paid, and it is proposed to make a return of 3s. per share to the shareholders. When the property came into the hands of the liquidator a large amount of the stock was in an unfinished condition. After careful consideration it was determined to complete as many dynamos as possible before offering them for sale. Several offers were received for part of the plant and stock by private treaty, but the difficulty of fixing prices being considerable, and some of the offers received being absurdly small, it was decided, with the full concurrence of the committee, that all should be offered by public auction, excepting sales at current prices. In accordance with that decision, the whole of the plant, stock, and apparatus at the factory in Appold-street, at the stores in Bermondsey-street, at the lamp factory in Bermondsey, and at the Electrical College in Red Lion-square, were offered for sale at public auction, the sale occupying seven days. The amount realised, after deducting the heavy expenses and the auctioneer's charges, was £11,604. 4s. The wisdom of the policy adopted, and of making so much of the sale as was done by extended advertising, was then fully manifested. The Anglo-American Brush Company's concessions and the Ferranti patents were offered at the auction sale, but no bids were made. Sales, however, have been effected subsequently at low prices. Under an agreement with Messrs. Donnithorne and Liardet, £5,695 had been deposited with Messrs. Hoare, the bankers, as a guarantee fund in connection with a contract. After referring to the legal proceedings between Messrs. Donnithorne and Liardet and the Company, in connection with this contract, he continued: Early in August, 1885, the action was dismissed with costs, and the deposit, with interest, amounting in all to £6,099. 13s. 9d., was ordered to be paid to me as liquidator. This was received on 19th November, 1885. In addition to the ordinary creditors for goods, &c., various claims arose out of royalty and other contracts; also heavy claims and complications arose in connection with the various leases held by the Company. I was enabled to settle all of these claims on favourable terms, and to get

Digitized by Google

the Company relieved of the claims on the leases. The claims of the debenture holders, which were carrying interest at the rate of 7 per cent. per annum, were discharged under an order of the Court in January, 1886, thus stopping interest at that early date. The list of the other creditors having been settled by the Court, notice of payment in full was given in May, 1886, and all have been discharged. The provisional cash statement herewith presented exhibits the amount obtained for the various properties of the Company in a summary form only, but I shall be happy to supply such details as the shareholders may desire. The result of the liquidation shows that after paying the debenture holders and creditors' claims, amounting to £15,246, there remains a balance in hand of £8,583. There are, however, a few paper assets still to be dealt with before the liquidation can be finally closed. In conclusion, it only remains for me to remind you that when I was first appointed it was not expected that the work of the liquidation would have entailed such unremitting and personal labour, or that it would turn out so favourably to the shareholders as it has done. In view of this, your liquidator was induced to accept a fee of 600 guineas. The result of the liquidation, however, entitles him, according to the scale fixed by the Court of Chancery, to a much higher rate of remuneration, which would, no doubt, be allowed upon application to the Court, but it would be some satisfaction to the liquidator if the meeting were to pass a resolution which would certify their appreciation of his services. It is upon the official basis of remuneration, as allowed by the Court, that the accounts now about to be laid before the meeting are made out, showing a balance of £8,583. 10s. 11d, and the liquidator proposes forthwith to make a return to the shareholders of 3s. per share, which will absorb £8,401. 1s. 0d, and thus practically close the liquidation.

After a few remarks from Mr. EDENSOR,

Mr. INCE warmly commended Mr. Theobald for the manner in which that gentleman had carried out the liquidation, and he proposed a resolution, increasing the personal remuneration of Mr. Theobald to 900 guineas, on the condition that 3s. a share was returned to the shareholders.

Mr. A. M'ALISTER said that the meeting must first deal with the report and accounts.

Mr. INCE said that in point of order Mr. M'Alister was right, and he would therefore propose the following resolution first—"Resolved that the report of the liquidator and the accounts of the liquidation be, and the same are hereby, received and adopted, and that, in view of the liquidator's report, this meeting is of opinion that the whole of the outstanding assets are irrecoverable and valueless, with the exception of the iron safe and office furniture, and that the liquidator be, and he is hereby, instructed to refrain from any further effort, and from incurring any further expense in connection with attempts to dispose of such outstanding assets, and that upon the completion of the winding up the said iron safe be retained by the liquidator for the purpose of preserving until such time as the Court sees fit the books and documents of the Company."

Mr. A. M'ALISTER seconded the resolutions. He as one of the Committee of Inspection had had the opportunity of seeing the way in which Mr. Theobald had worked, and the result was that, instead of receiving nothing, the shareholders would have 3s. a share. Instead of spinning out the liquidation for years, Mr. Theobald had worked to close it as soon as possible.

Mr. F. W. REYNOLDS said that the committee had found that it would be hopeless under the circumstances to reconstruct the Company. Mr. Theobald had done everything he possibly could for the shareholders. Possibly the Company came into existence rather too soon; but he believed that all present felt that there was a great future for electricity, not only in regard to lighting, but also as a motive power.

The CHAIRMAN, in reply to a question, said that the money was all in hand, and he proposed to distribute it as soon as the circular could be sent out.

The SOLICITOR then read the resolutions, which were separately agreed to *nem. con.*

The meeting then terminated.

The Brazilian Submarine Telegraph Company.

The following is the report of the Directors for the half-year ended 30th June, 1887, to be submitted to the twenty-eighth ordinary general meeting to be held on 2nd November, at Winchester House, Old Broad-street, E.C., at 12 noon :—

The revenue for this period amounted to £100,876. 7s. 6d., and the working expenses to £13,262. 2s. 10d. After providing £14,205 for debenture interest and sinking funds, and £2,004. 17s. 6d. for income-tax, there remains a balance of £71,404. 7s. 2d.; to this is added £7,528. 5s. 1d. brought forward from 31st December last, making a total of £78,932. 12s. 3d. A quarterly interim dividend amounting to £19,500 has been paid, and £25,000 transferred to the reserve fund, leaving a balance of £34,432. 12s. 3d. The directors now recommend the declaration of a final dividend of 3s. per share, making, with the interim dividends, a total dividend of six per cent. for the year, and also the payment of a bonus of 2s. per share, both free of income-tax, which together will amount to £32,500, being a distribution in the aggregate of 7 per cent. for the past year, leaving a balance of £1,932. 12s. 3d. to be carried forward. On the 30th July last the sum of £37,100 was transferred from the sinking fund to pay off the 371 bonds of the 1884 issue, drawn for redemption in April last. This repayment reduces the debenture debt to £187,900. The various sections of the Company's line are in good working order.

Sir James Anderson and the Hon. W. St. John F. Brodrick, M.P., retire by rotation at this meeting, and, being eligible for re-election as Directors, offer themselves accordingly. The two auditors, Mr. Henry Dever and Mr. John Gane, also offer themselves for re-election.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 21st October amounted to £4,270.

CENTRAL AND SOUTH AMERICAN TELEGRAPH COMPANY.—This company has declared a quarterly dividend of 1½ per cent., leaving a sum of $12,500 to be carried forward.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—This company give notice that the coupon on their Five per Cent. Manila Debentures (1880 issue) due on the 1st November proximo, will be payable on and after that date on presentation of the same at the Consolidated Bank, 52, Threadneedle-street, E.C. Coupons must be left three clear days for examination.

INDO-EUROPEAN TELEGRAPH COMPANY.—The directors of this company have declared an interim dividend for the half year ended the 30th June last at the rate of 5 per cent. per annum, being the same as for the first half of 1886.

MEXICAN TELEGRAPH COMPANY.—The Mexican Telegraph Company has declared a quarterly dividend of 2½ per cent., leaving a surplus carried forward of $11,000.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 21st October, 1887, were £3,316, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—At a meeting of the directors of this company, held on the 26th inst., it was decided to recommend to the shareholders at the approaching meeting that a dividend of 9s. per share be declared on account of arrears of dividend on the First Preference Shares.

PERSONAL.—Mr. J. H. Cundall, M.I.C.E, has taken offices at 121, Cannon-street, E.C., and commenced business as a Consulting Electrical Engineer. Many electricians will recollect that Mr. Cundall organised and superintended the lighting of the Indian and Colonial Exhibition, and the success which attended his efforts upon that occasion should go a long way towards assuring him ample support in his new career.

——— Mr. Arthur Morley, of Radcliffe-street, Islington, trading as The Vulcan Manufacturing Company, informs us that Mr. Wilson has retired from the business.

NOTES.

BRUSSELS.—A considerable length of the phosphor bronze telephone line between Paris and Brussels has been torn down by the recent gales.

LONDONDERRY.—The Corporation of Londonderry are inviting tenders for the supply of electric light. Particulars may be found in another column.

THE CARLTON CLUB.—The Carlton Club, which was re-opened this week, is now lit by Ferranti transformers, from the Grosvenor Gallery Central Station.

THE WAR OF CABLE RATES.—It is believed in cable circles that the visit of Mr. Jay Gould to this country will lead to an arrangement between the rival companies.

THE BRIGHTON ELECTRIC RAILWAY.—We regret to learn, at the moment of going to press, that the severe south-westerly gale of Thursday has caused very serious damage to Magnus Volk's Electric Railway.

TWO MEN KILLED BY LIGHTNING.—On Sunday night at Carahboge, between Killorglin and Glenbeigh, a farmer named Walsh was, during a storm, tying a cow up in a shed, his eldest son standing some yards off, when a flash of lightning came, and the two men and the cow were struck dead.

ELECTRIC TRACTION AT RICHMOND. — Messrs. Christi, James and Co.—who, we understand, are acting in this matter as the agents of a French firm—have been making experiments during the present week with a tramcar propelled by secondary batteries on the line between Kew Bridge and Richmond. We shall probably be in a position to give further details next week.

APPOINTMENT.—Mr. Samuel Vyle, of Glasgow, has received the appointment of Electrician to the Post Office of British Guiana, an office which involves the responsibility of the technical charge of the Government land lines and cables of that colony. Mr. Vyle will leave Glasgow for British Guiana about the 26th inst., and his departure will be regretted by a numerous circle of friends.

DISTURBED IRELAND.—The police authorities have issued notices throughout West Clare in reference to the cutting down of the telegraph wires between Kilrush and Ennis last Sunday. It is stated that in future where such outrages are attempted a police hut will be erected on the scene of the occurrence, and the parish will be taxed with the cost of the constabulary stationed at the hut.

HALIFAX (N.S.).—It is stated that the cable steamer "Britannia" is about to move the shore ends of the Direct United States Company's cables from Tor Bay to Halifax, which is ninety miles further South. The "Britannia" has on board the necessary lengths of new cable. The general tendency appears now to be in favour of bringing cables ashore as close as possible to the most important towns of the coast-line, instead of landing them on uninhabited spots.

TELEGRAPH STORES REQUIRED.—The directors of the South Indian Railway Company advertise for tenders for telegraph stores. Specifications (price 10s.) may be obtained from the Managing Director, 55, Gracechurch-street, E.C., and tenders must be returned by November 15.—The Cheshire Lines Committee also advertise for tenders for telegraph stores, including wire and instruments. Specifications may be obtained from Mr. W. H. Legge, storekeeper, Warrington, and tenders must be returned by December 3.

ELECTRIC WELDING.—Messrs. Laing, Wharton and Down write us as follows:—"We notice in your issue of the 21st ult. a notice relating to 'Electric Welding in Germany,' and in this connection we have to say that we are informed that active measures are being taken in that country to organise a strong syndicate to put in operation Prof. Elihu Thompson's electric welding apparatus, on which he has very valid patents, and power is now being placed for the working of welding plant, which is now on the way and will soon be in practical use."

BLACKPOOL.—The directors of the Blackpool Electric Tramcar Company held a field day on Friday last. The promenade was hung with arc lights, in which eight different systems were represented, and the tramcars themselves, as the local reporter says, "were brilliantly illuminated by the same agency." Afterwards there was a dinner, at which the Mayor of Blackpool presided, and amongst other distinguished guests there were present Mr. Alexander Siemens, the Mayors of Manchester and Halifax, and Mr. J. Oddey, an ex-mayor of Ballarat.

TUESDAY'S GALE.—Notwithstanding the violence of the gale which swept across the greater portion of England on Tuesday last, comparatively little damage seems to have been done to telegraph and telephone plant, although other kinds of property suffered severely. At Blackburn, where it was exceptionally furious, some of the wires were blown down, interrupting communication between the town and other places for about two hours. Beyond these and the destruction of one or two electric lamps at the Newcastle Exhibition no other casualties in electrical property have been reported.

THE CHANNEL CABLES.—It is stated that the Chamber of Commerce at Havre has addressed to the French Government a protest against the renewal of the monopoly to the Submarine Telegraph Company. Protests of a similar character are likely to come from Paris, Bordeaux, Rheims, and other towns. It is a little surprising that no movement has yet been made on this side of the Channel, but probably there is a feeling that the danger of the renewal of the monopoly is too remote to give cause for alarm. Still, it would be as well for those chiefly interested not to lose sight of the matter until the question has been finally set at rest.

THE LIGHTING OF THE MILE END INFIRMARY.—The Mile End Board of Guardians has obtained a report on the cost of providing their infirmary with electric light. It appears that motive power is already available in the shape of an engine employed at present for chopping wood, and hence a considerable economy is expected. The present cost of gas lighting is £356, and the estimated expenditure for electric light is £200 per annum. While it would be rash to express any opinion on these figures without knowing something more of the conditions, on the surface it is difficult to understand how the saving of £156 is to be effected, even with the engine thrown in. We make this observation in the interests of all concerned.

THE SOCIETY OF ENGINEERS.—At the next ordinary meeting of this society, to be held on Monday, 7th November, at 7:30 p.m., at the Westminster Town Hall, a paper will be read on "Primary Batteries for Illuminating Purposes," by Mr. Perry F. Nursey, past president, of which the following is a synopsis:—"Introduction. A wide field open for primary batteries. Their principles and history outlined. Descriptions of batteries for special purposes, and batteries for general lighting, including those of Holmes and Burke, Ross, Coad,

Digitized by Google

lutely no cross talk from one wire to the other, and conversation could be carried on freely and without any more effort than on an air line. The introduction of an annunciator drop into the circuit made no difference. A test for insulation showed 400,000 ohms for the distance and a static capacity of 1·4 microfarad. A week later the same wires were used in the same manner with less satisfactory results. The weather was dry and warm. It was found that counting on one could be distinctly followed on the other, and *vice versâ*. The cross talk from the other wires was very noticeable, but not of sufficient volume to disturb the user. Conversation at a distance of eight inches from a fairly adjusted transmitter was indistinct and muffled. With the lips close to the transmitter, and by speaking in the usual tone of voice, the results were fairly satisfactory. This was particularly true when an air line of one and a-half mile was added. The measurements made after the test showed the insulation to be 4 megohms for the distance, against ·4 of a megohm on the previous test, and 1·05 microfarad capacity against 1·4. By opening one of the wires at both ends, so that all connection with the earth was removed, conversation could be freely carried on between three parties who were looped in. The first one was 5,000ft. from the open end of the cable, and the other 12,000ft. The only difference noted by the intermediate parties in the working of the wires with the ends open was that the cross talk was much heavier than with the grounds on. The second test indicates conclusively that we have used up all of our margin and that a slight addition to the length of the cables will make the connection of no commercial value. In fact, in ordinary dry, clear weather, conversation is only carried on by frequent repetitions and considerable discomfort. The nine cables included in this test are all in good condition, and with the exception of a few pieces of air cable, are new. On the above circuit there are sixteen terminals in use, but in all cases, except in exchange offices, the cable wires of one cable were connected with those of another at the terminals with kerite or okonite wire, so that the insulation was good at these points. The experience of four years has proved the fallacy of the practice of requiring the manufacturers to furnish a cable showing an insulation of from 300 to 800 megohms per mile. While this insulation can be secured immediately upon the completion of a cable, it is utterly impossible to maintain it. Nor is it desirable to maintain it, for the reason that cross talk is greater on a cable with a "fancy" insulation than in one of a megohm. Subscribers always complain of cross talk when their wires are put into a new cable, but after a few months we hear no more about it. This is not so much because they have become accustomed to the cross talk as it is that with the lowering of the insulation the cross talk is decreased. A better specification would be one megohm per mile and not more than five, and a guarantee from the manufacturer that this insulation will hold up for ten years. Such an insulation exceeds anything that we are able to get on air lines. In a recent test nine wires showed each an insulation of 5·3 megohms. Rain began to fall, and it ten minutes the insulation had fallen off to 3·2, and no doubt went lower. This illustrates the extreme sensitiveness of a high insulation to moisture, and indicates clearly that where there is a large number of cables in use the conditions are constantly varying, and nothing like uniformity in the working of the wires can be expected or secured.

ON JOINING LEAD-COVERED CABLES.

BY MR. PATTERSON.

The only thing to look out for in making a joint in a lead-covered cable is to keep out moisture. The ends of the cable, after the cable is made, should always be sorted out. Then after the cable is drawn into a conduit, the end of the pipe is cut off and the pipe removed from the core for a distance back corresponding to the size of the cable. For a 100-wire cable we would want to strip about 18 or 24 inches on each end. On the new style of cables arranged for metallic circuit each pair of conductors are twisted together and served with a single splint of cotton. The serving around the two wires will hold them in place until the man who is doing the splicing deliberately removes it. One is covered with white cotton and one with red and white—some colour that can be easily distinguished. The two wires are brought together, and the way we generally make a splice, and the best way, I think, is to strip the wires for an inch and a-half, bring them together, and instead of making a long splice, bend them up and then twist the ends together. That will leave the wire running through and the two ends twisted together standing at right angles to it. A cotton sleeve is drawn over it. This sleeve is like the outer braiding of office wire. After all the wires are spliced in that way they should receive a bath in very hot paraffin, poured on while they are laid out loosely to remove moisture, which they may gather from the atmosphere and from the hands of the men. Then the core should be covered and brought down to a compact size, that the lead sleeve will slip back over it. After that sleeve is on it should receive another paraffin bath. After the work is all done it is well to take a torch or something of the kind and pass it along underneath the cable and melt the insulation for a distance of one or two feet each side, so as to put on a pressure and test the joints; if there is any flaw it will show itself by the paraffin oozing when the pressure is put on. Occasionally, in underground work, it is not convenient to make a sleeved pipe. In that case we turn both ends of the cable up and bring them out through the top and have a brass casting in the form of an inverted Y. The two branches of the Y are of such size that the cable pipe will slip into them, and the main outlet is large enough to make the splice. The wires are brought up through it and spliced together, and the opening covered by a cap. After the work is done, that Y is dropped down into the hole and lifted. That removes the necessity of doing the work in the manhole. It is lifted up to the level of the street, and the man sits on the edge with his feet inside and works on it.

COMPANIES' MEETINGS & REPORTS.

The Eastern Extension, Australasia, and China Telegraph Company (Limited).

The twenty-eighth ordinary general meeting of this Company was held on Wednesday, 26th October, at Winchester House, 50, Old Broad-street, Mr. John Pender in the chair.

The SECRETARY (Mr. F. E. Hesse) read the notice convening the meeting and the minutes of the previous meeting, which were confirmed and signed by the Chairman as correct. The report and accounts were taken as read.

The CHAIRMAN: I will, with your permission, now give you a few details as to the last half year's working. The gross receipts for the half year were £219,201, against £224,843 for the corresponding period of 1886, or a decrease of £5,642. This result, however, is not unsatisfactory having regard to the fact that in the corresponding period the reduced tariffs had not come into operation. The reductions agreed to at Berlin were, however, based on the figures of 1884 and 1885, which were the best years we have ever had, and although we shall this year carry a larger number of words than in 1884, we shall have only made up about £18,000 of the loss of £50,000 per annum, which was estimated from the reduced tariffs, leaving over £30,000 still to be recouped. As the traffic is increasing this loss will doubtless be made up in course of time; but our experience shows that the traffic does not respond so readily as the advocates of low tariffs would have us believe. The expenses for the half year were £76,241, against £81,775 for the corresponding period of 1886, showing a decrease of £5,534, which is due to our having disposed of the "Agnes," and having consequently had during the past half year only two maintenance ships, against three in the corresponding period of 1886. The net revenue for the half year was £97,662, against £97,480 for the corresponding period of 1886, showing an increase of £182. One quarterly interim dividend of 1½ per cent. has been paid during the half year, and another of like amount was distributed on the 15th inst., leaving £35,162 to be carried forward to the current half year, at the end of which the question of bonus distribution will be dealt with. I have during the last week, since the report was issued, received six letters from shareholders on the subject of the printed accounts, three of them having reference to the non-payment of a bonus for the half year. It was, however, always understood that any bonus that might be declared should be paid at the end of the year after having ascertained the result of the year's operations. We were, however, at one time urged by some of our shareholders—in 1884 or 1885 I think it was—to make the distribution half-yearly, which we did for several years, but after the reduction that we had to submit to at Berlin we thought it was more desirable to postpone it till the end of the year. No doubt at the end of the current year we shall be able to pay a portion of it at all events, and thus redeem our promise as we did in previous years. There have been no serious interruptions to our system during the past half year, although numerous repairs have been effected, and all the sections, excepting the Tonquin-Hong Kong cable, which is at present undergoing repair, are now in good working order. Since the close of the half year under review a further portion of the Singapore-Saigon section, which is the only main cable unduplicated, has been renewed with brass-ribboned cable to the length of 174 nautical miles, leaving about 150 nautical miles to be renewed. This will, in all probability, be completed during the current half year, in which case the cost of the operation will be shown in the next published accounts.

This question of the renewal of cables, and the damage effected by the teredo is a very important one. We had for many years constant cause for repairs by the action of that insect, but we set our brains to work, and the result was that we hit upon a plan which has greatly obviated the difficulty, by using brass-ribboned cable. The following statistics will show the value of brass-ribboned cables in teredo-infested waters:—Before the Singapore-Batavia cable was renewed in 1881 no less than 194 faults were removed in 11 years, or on an average 18 a year; whereas, during the last six years only four breaks have occurred, and these have been entirely due to ships' anchors. On the Banjoewangie-Darwin cable 67 faults occurred before it was partially renewed in 1884, since which time not one fault has occurred in the brass-ribboned portion. The same remark applies to the Singapore-Saigon cable, which was partially renewed in 1885, although forty-nine faults had previously occurred. Consequently our experience, extending over a period of nearly seven years, clearly shows that

Digitized by Google

the brass-ribboned cable has successfully resisted the attacks of the teredo, from which we sustained so much damage until we adopted this valuable form of protection. The Company's new shore cable establishment at Singapore, in place of the hulk, "Southern Ocean," has been completed, and the tanks and machinery from the latter were transferred to the shore establishment before the hulk was sold by public auction.

At the last meeting I went fully into the details of our relations with the Australian colonies and New Zealand, and have now only to state that during the last six months, since the return of the delegates to their respective homes and Governments, nothing has been done. At the end of next month, I believe, there is to be a conference at Adelaide to consider the question of cheaper postal rates and lower telegraph rates between the mother country and the colonies; and until the Directors hear of the decision arrived at their policy will be to leave things alone. Since the last meeting of the Company a fresh Parliament has been elected in New Zealand, and the Government from whom the Company had differed were out of power. As soon as their successors have had a little time to settle down the Directors will resume the correspondence, with, I hope, a fair prospect of success. The Company have been in negotiation with the Chinese Government during the half year, and have tried to show that Government that submarine telegraphs were a great necessity for China, and the Chinese Government endeavoured to prove that land lines would beat the submarine system. The result has been that an understanding has been come to by which both interests will be properly protected. The points of the agreement have been settled, and it simply awaits the approval of the Chinese Foreign Office; and when that matter is settled I hope that for the next sixteen years we shall be able to look at the growth in the China trade without any fear of undue competition. I may mention that nearly the whole of our system is duplicated—I might almost say, triplicated—so that we are in every way in an efficient condition for the conduct of our business. Our relations with the Imperial and Colonial Governments are of the most friendly nature. The other day the Imperial Government laid down a cable to Port Hamilton, which they afterwards found they did not require, and we took the opportunity to take it off their hands at such a price as would enable us to utilise it with advantage. I think that I have gone over all the points that it is necessary to call your attention to, and I will finish by saying that our relations with all foreign Governments are very satisfactory and our revenue is increasing, and I hope by the time we meet you six months hence we shall be able to show that there has been considerable progress for the half year, and that we shall be able to resume the payment of the bonus. I will conclude by formally moving the adoption of the report and accounts.

The Most Hon. the Marquis of TWEEDDALE seconded the motion, which was carried unanimously.

A vote of thanks was afterwards passed to the Chairman and Directors, and the proceedings terminated.

Hammond Electric Light and Power Supply Company (Limited) (in Liquidation).

An extraordinary general meeting of this Company was held at Winchester House, Old Broad-street, yesterday (Thursday), under the presidency of Mr. William Theobald (the liquidator).

The SOLICITOR having read the notice convening the meeting,

The CHAIRMAN, in the course of his remarks, said: I feel that before I go to the report I should refer to the circular issued in April last, stating that we should probably call a meeting in the following June. Soon after that circular was issued I found, on looking into the matters outstanding, that they were so few and of such little value that if I deferred calling the shareholders together for a little while, I should be able to place before you the final accounts, and that I am able to do to-day. I have the pleasure of presenting the following report upon my duties as liquidator, which I venture to think will reveal a more satisfactory result than was at one time anticipated. On the 10th of June, 1885, I was appointed by the Chancery Division of the High Court of Justice provisional liquidator of your Company, with power to carry on the business, so far as was necessary for carrying out and completing existing contracts, and to pay wages and other charges. On the seventeenth day of the same month, at an extraordinary general meeting of the members it was resolved that the company should be wound up voluntarily, and I was appointed liquidator. The following shareholders were at the same time appointed a consulting and advising committee, viz.:—Messrs. E. H. Brown, A. M'Alister, and F. W. Reynolds. Immediately on taking possession of the assets and undertakings of the Company, including as they did important uncompleted contracts, it became apparent that many of them were of a very special character, their advantageous realisation demanding personal and most careful consideration, and I have to acknowledge the valuable assistance which was afforded me at this time by the advising committee. Valuable assistance was also rendered from time to time throughout the proceedings by Mr. Robert Hammond, which has been of substantial service to the liquidation. The peculiar nature of the difficulties attending the realisation of some of the assets may be best exhibited by a few examples [which he proceeded to give]. A lighting station at Brighton had been worked for some time, but was in a very incomplete state, and under the conditions of the lease certain of the engines used for driving the dynamos had to be removed. Although there seemed every probability that by expenditure of additional capital the lighting station might be placed on a profitable basis, it was doubtful if at that time it was paying expenses. A contract for management for a term of years had been entered into with the Eastbourne Electric Light Company (Limited), under which the Hammond Company were to bear all losses or take the profits, if any, on the working; they were also to provide the requisite capital for extension purposes, and to receive payment in debentures of the Eastbourne Company. A similar contract had also been entered into with the Hastings and St. Leonards-on-Sea Electric Light Company (Limited). Under the two last-mentioned contracts the Hammond Company had become entitled to debentures of the Eastbourne Company for about £7,050, and of the Hastings and St. Leonards Company for about £3,300. In the case of the Eastbourne Company the debentures, jointly with others to the extent of £500, formed a first charge upon the assets of the Company; but in the case of the Hastings Company the debentures only ranked after a charge for £4,000 given to the bankers. Neither of the above companies were paying expenses; and after careful consideration it was decided to risk the refusal of supplies to the Hastings Company (fortunately without causing a stoppage of their business), but to carry on the Eastbourne contract for a time in the hope of obtaining a purchaser for the debentures, who would also undertake to perform the contract. With this object in view the liquidator made overtures to the Anglo-American Brush, the Edison and Swan, and other electric light companies. Protracted negotiations and correspondence also were carried on with the representatives of all the various interests concerned, but without satisfactory result; and after long and tedious efforts to sell by private treaty it was determined to offer for sale by public tender not only the Brighton Lighting Station, the Hammond Company's interests in the Hastings and St. Leonards-on-Sea Electric Light Company, and the Eastbourne Electric Light Company, but also what remained of the hiring installations in other parts of the country. Advantage was taken of the issue of a circular by the Consulting Committee on the 16th September, 1885, to forward a copy of the advertisement of this sale to every shareholder on the register. Offers were received for each of the properties mentioned, some of which were immediately accepted, but in other instances improved prices were obtained by subsequent negotiations. The issue of the tender forms and the acceptance of each offer were made with the approval and under the direction of the Court. I found it impossible to arrange any scheme for the reconstruction of the Company; and as inquiries are still occasionally made on the subject, I cannot do better than quote from the circular of the committee above referred to, in which they say:—"Since you appointed us to confer with your liquidator, we have carefully considered the possibility of a resuscitation of your Company, and we regret that we are unable to recommend such a course. The large amount of liabilities and claims, about £20,000, and the peculiar nature of the assets, would necessitate an immediate subscription of considerable capital, which we do not feel justified in asking the shareholders to find." They added—"We fear the prospect of any return being made to the shareholders is extremely doubtful." Since issuing this circular in September, 1885, the committee have taken no part in the management of the liquidation, feeling that the shareholders were not likely to obtain any benefit from their labours, and having at the meeting convened by the above circular resigned their position. Another of the undertakings in connection with, and, in fact, forming part of the Hammond Company, which at one time seemed likely to involve many troublesome claims for uncompleted contracts, was the Electrical College, in Red Lion-square. Having explained the steps taken in this matter, he added:—All the claims from the parents and guardians of the students, which at one time seemed inevitable, were avoided. Not one claim was sustained, and I believe general satisfaction was given. In conducting the liquidation it was often difficult to decide how far it was advisable to carry out contracts for work on hand and hiring contracts, and whether less loss would be incurred by breach of the contract than by completing it. The labour of realising the estate and in settling the claims has been much heavier than was at first anticipated. It is a source of pleasure to me, therefore, to be able to report that, whereas at one time it seemed doubtful if even the creditors would be paid in full, I am able to report to-day that they have all been paid, and it is proposed to make a return of 3s. per share to the shareholders. When the property came into the hands of the liquidator a large amount of the stock was in an unfinished condition. After careful consideration it was determined to complete as many dynamos as possible before offering them for sale. Several offers were received for part of the plant and stock by private treaty, but the difficulty of fixing prices being considerable, and some of the offers received being absurdly small, it was decided, with the full concurrence of the committee, that all should be offered by public auction, excepting sales at current prices. In accordance with that decision, the whole of the plant, stock, and apparatus at the factory in Appold-street, at the stores in Bermondsey-street, at the lamp factory in Bermondsey, and at the Electrical College in Red Lion-square, were offered for sale at public auction, the sale occupying seven days. The amount realised, after deducting the heavy expenses and the auctioneer's charges, was £11,604. 4s. The wisdom of the policy adopted, and of making so much of the sale as was done by extended advertising, was then fully manifested. The Anglo-American Brush Company's concessions and the Ferranti patents were offered at the auction sale, but no bids were made. Sales, however, have been effected subsequently at low prices. Under an agreement with Messrs. Donnithorne and Liardet, £5,695 had been deposited with Messrs. Hoare, the bankers, as a guarantee fund in connection with a contract. After referring to the legal proceedings between Messrs. Donnithorne and Liardet and the Company, in connection with this contract, he continued: Early in August, 1885, the action was dismissed with costs, and the deposit, with interest, amounting in all to £6,099. 13s. 9d., was ordered to be paid to me as liquidator. This was received on 19th November, 1885. In addition to the ordinary creditors for goods, &c., various claims arose out of royalty and other contracts; also heavy claims and complications arose in connection with the various leases held by the Company. I was enabled to settle all of these claims on favourable terms, and to get

Digitized by Google

the Company relieved of the claims on the leases. The claims of the debenture holders, which were carrying interest at the rate of 7 per cent. per annum, were discharged under an order of the Court in January, 1886, thus stopping interest at that early date. The list of the other creditors having been settled by the Court, notice of payment in full was given in May, 1886, and all have been discharged. The provisional cash statement herewith presented exhibits the amount obtained for the various properties of the Company in a summary form only, but I shall be happy to supply such details as the shareholders may desire. The result of the liquidation shows that after paying the debenture holders and creditors' claims, amounting to £15,246, there remains a balance in hand of £8,583. There are, however, a few paper assets still to be dealt with before the liquidation can be finally closed. In conclusion, it only remains for me to remind you that when I was first appointed it was not expected that the work of the liquidation would have entailed such unremitting and personal labour, or that it would turn out so favourably to the shareholders as it has done. In view of this, your liquidator was induced to accept a fee of 600 guineas. The result of the liquidation, however, entitles him, according to the scale fixed by the Court of Chancery, to a much higher rate of remuneration, which would, no doubt, be allowed upon application to the Court, but it would be some satisfaction to the liquidator if the meeting were to pass a resolution which would certify their appreciation of his services. It is upon the official basis of remuneration, as allowed by the Court, that the accounts now about to be laid before the meeting are made out, showing a balance of £8,583. 10s. 11d, and the liquidator proposes forthwith to make a return to the shareholders of 3s. per share, which will absorb £8,401. 1s. 0d, and thus practically close the liquidation.

After a few remarks from Mr. EDENSOR,

Mr. INCE warmly commended Mr. Theobald for the manner in which that gentleman had carried out the liquidation, and he proposed a resolution, increasing the personal remuneration of Mr. Theobald to 900 guineas, on the condition that 3s. a share was returned to the shareholders.

Mr. A. M'ALISTER said that the meeting must first deal with the report and accounts.

Mr. INCE said that in point of order Mr. M'Alister was right, and he would therefore propose the following resolution first—"Resolved that the report of the liquidator and the accounts of the liquidation be, and the same are hereby, received and adopted, and that, in view of the liquidator's report, this meeting is of opinion that the whole of the outstanding assets are irrecoverable and valueless, with the exception of the iron safe and office furniture, and that the liquidator be, and he is hereby, instructed to refrain from any further effort, and from incurring any further expense in connection with attempts to dispose of such outstanding assets, and that upon the completion of the winding up the said iron safe be retained by the liquidator for the purpose of preserving until such time as the Court sees fit the books and documents of the Company."

Mr. A. M'ALISTER seconded the resolutions. He as one of the Committee of Inspection had had the opportunity of seeing the way in which Mr. Theobald had worked, and the result was that, instead of receiving nothing, the shareholders would have 3s. a share. Instead of spinning out the liquidation for years, Mr. Theobald had worked to close it as soon as possible.

Mr. F. W. REYNOLDS said that the committee had found that it would be hopeless under the circumstances to reconstruct the Company. Mr. Theobald had done everything he possibly could for the shareholders. Possibly the Company came into existence rather too soon; but he believed that all present felt that there was a great future for electricity, not only in regard to lighting, but also as a motive power.

The CHAIRMAN, in reply to a question, said that the money was all in hand, and he proposed to distribute it as soon as the circular could be sent out.

The SOLICITOR then read the resolutions, which were separately agreed to *nem. con.*

The meeting then terminated.

The Brazilian Submarine Telegraph Company.

The following is the report of the Directors for the half-year ended 30th June, 1887, to be submitted to the twenty-eighth ordinary general meeting to be held on 2nd November, at Winchester House, Old Broad-street, E.C., at 12 noon :—

The revenue for this period amounted to £100,876. 7s. 6d., and the working expenses to £13,262. 2s. 10d. After providing £14,205 for debenture interest and sinking funds, and £2,004. 17s. 6d. for income-tax, there remains a balance of £71,404. 7s. 2d.; to this is added £7,528. 5s. 1d. brought forward from 31st December last, making a total of £78,932. 12s. 3d. A quarterly interim dividend amounting to £19,500 has been paid, and £25,000 transferred to the reserve fund, leaving a balance of £34,432. 12s. 3d. The directors now recommend the declaration of a final dividend of 3s. per share, making, with the interim dividends, a total dividend of six per cent. for the year, and also the payment of a bonus of 2s. per share, both free of income-tax, which together will amount to £32,500, being a distribution in the aggregate of 7 per cent. for the past year, leaving a balance of £1,932. 12s. 3d. to be carried forward. On the 30th July last the sum of £37,100 was transferred from the sinking fund to pay off the 371 bonds of the 1884 issue, drawn for redemption in April last. This repayment reduces the debenture debt to £187,900. The various sections of the Company's line are in good working order.

Sir James Anderson and the Hon. W. St. John F. Brodrick, M.P., retire by rotation at this meeting, and, being eligible for re-election as Directors, offer themselves accordingly. The two auditors, Mr. Henry Dever and Mr. John Gane, also offer themselves for re-election.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 21st October amounted to £4,270.

CENTRAL AND SOUTH AMERICAN TELEGRAPH COMPANY.—This company has declared a quarterly dividend of 1½ per cent., leaving a sum of $12,500 to be carried forward.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—This company give notice that the coupon on their Five per Cent. Manila Debentures (1880 issue) due on the 1st November proximo, will be payable on and after that date on presentation of the same at the Consolidated Bank, 52, Threadneedle-street, E.C. Coupons must be left three clear days for examination.

INDO-EUROPEAN TELEGRAPH COMPANY.—The directors of this company have declared an interim dividend for the half year ended the 30th June last at the rate of 5 per cent. per annum, being the same as for the first half of 1886.

MEXICAN TELEGRAPH COMPANY.—The Mexican Telegraph Company has declared a quarterly dividend of 2½ per cent., leaving a surplus carried forward of $11,000.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 21st October, 1887, were £3,316, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—At a meeting of the directors of this company, held on the 26th inst., it was decided to recommend to the shareholders at the approaching meeting that a dividend of 9s. per share be declared on account of arrears of dividend on the First Preference Shares.

PERSONAL.—Mr. J. H. Cundall, M.I.C.E, has taken offices at 121, Cannon-street, E.C., and commenced business as a Consulting Electrical Engineer. Many electricians will recollect that Mr. Cundall organised and superintended the lighting of the Indian and Colonial Exhibition, and the success which attended his efforts upon that occasion should go a long way towards assuring him ample support in his new career.

——— Mr. Arthur Morley, of Rodliffe-street, Islington, trading as The Vulcan Manufacturing Company, informs us that Mr. Wilson has retired from the business.

NOTES.

BRUSSELS.—A considerable length of the phosphor bronze telephone line between Paris and Brussels has been torn down by the recent gales.

LONDONDERRY.—The Corporation of Londonderry are inviting tenders for the supply of electric light. Particulars may be found in another column.

THE CARLTON CLUB.—The Carlton Club, which was re-opened this week, is now lit by Ferranti transformers, from the Grosvenor Gallery Central Station.

THE WAR OF CABLE RATES.—It is believed in cable circles that the visit of Mr. Jay Gould to this country will lead to an arrangement between the rival companies.

THE BRIGHTON ELECTRIC RAILWAY.—We regret to learn, at the moment of going to press, that the severe south-westerly gale of Thursday has caused very serious damage to Magnus Volk's Electric Railway.

TWO MEN KILLED BY LIGHTNING.—On Sunday night at Carahboge, between Killorglin and Glenbeigh, a farmer named Walsh was, during a storm, tying a cow up in a shed, his eldest son standing some yards off, when a flash of lightning came, and the two men and the cow were struck dead.

ELECTRIC TRACTION AT RICHMOND. — Messrs. Christi, James and Co.—who, we understand, are acting in this matter as the agents of a French firm—have been making experiments during the present week with a tramcar propelled by secondary batteries on the line between Kew Bridge and Richmond. We shall probably be in a position to give further details next week.

APPOINTMENT.—Mr. Samuel Vyle, of Glasgow, has received the appointment of Electrician to the Post Office of British Guiana, an office which involves the responsibility of the technical charge of the Government land lines and cables of that colony. Mr. Vyle will leave Glasgow for British Guiana about the 26th inst., and his departure will be regretted by a numerous circle of friends.

DISTURBED IRELAND.—The police authorities have issued notices throughout West Clare in reference to the cutting down of the telegraph wires between Kilrush and Ennis last Sunday. It is stated that in future where such outrages are attempted a police hut will be erected on the scene of the occurrence, and the parish will be taxed with the cost of the constabulary stationed at the hut.

HALIFAX (N.S.).—It is stated that the cable steamer "Britannia" is about to move the shore ends of the Direct United States Company's cables from Tor Bay to Halifax, which is ninety miles further South. The "Britannia" has on board the necessary lengths of new cable. The general tendency appears now to be in favour of bringing cables ashore as close as possible to the most important towns of the coast-line, instead of landing them on uninhabited spots.

TELEGRAPH STORES REQUIRED.—The directors of the South Indian Railway Company advertise for tenders for telegraph stores. Specifications (price 10s.) may be obtained from the Managing Director, 55, Gracechurch-street, E.C., and tenders must be returned by November 15.—The Cheshire Lines Committee also advertise for tenders for telegraph stores, including wire and instruments. Specifications may be obtained from Mr. W. H. Legge, storekeeper, Warrington, and tenders must be returned by December 3.

ELECTRIC WELDING.—Messrs. Laing, Wharton and Down write us as follows:—"We notice in your issue of the 21st ult. a notice relating to 'Electric Welding in Germany,' and in this connection we have to say that we are informed that active measures are being taken in that country to organise a strong syndicate to put in operation Prof. Elihu Thompson's electric welding apparatus, on which he has very valid patents, and power is now being placed for the working of welding plant, which is now on the way and will soon be in practical use."

BLACKPOOL.—The directors of the Blackpool Electric Tramcar Company held a field day on Friday last. The promenade was hung with arc lights, in which eight different systems were represented, and the tramcars themselves, as the local reporter says, "were brilliantly illuminated by the same agency." Afterwards there was a dinner, at which the Mayor of Blackpool presided, and amongst other distinguished guests there were present Mr. Alexander Siemens, the Mayors of Manchester and Halifax, and Mr. J. Oddey, an ex-mayor of Ballarat.

TUESDAY'S GALE.—Notwithstanding the violence of the gale which swept across the greater portion of England on Tuesday last, comparatively little damage seems to have been done to telegraph and telephone plant, although other kinds of property suffered severely. At Blackburn, where it was exceptionally furious, some of the wires were blown down, interrupting communication between the town and other places for about two hours. Beyond these and the destruction of one or two electric lamps at the Newcastle Exhibition no other casualties in electrical property have been reported.

THE CHANNEL CABLES.—It is stated that the Chamber of Commerce at Havre has addressed to the French Government a protest against the renewal of the monopoly to the Submarine Telegraph Company. Protests of a similar character are likely to come from Paris, Bordeaux, Rheims, and other towns. It is a little surprising that no movement has yet been made on this side of the Channel, but probably there is a feeling that the danger of the renewal of the monopoly is too remote to give cause for alarm. Still, it would be as well for those chiefly interested not to lose sight of the matter until the question has been finally set at rest.

THE LIGHTING OF THE MILE END INFIRMARY.—The Mile End Board of Guardians has obtained a report on the cost of providing their infirmary with electric light. It appears that motive power is already available in the shape of an engine employed at present for chopping wood, and hence a considerable economy is expected. The present cost of gas lighting is £356, and the estimated expenditure for electric light is £200 per annum. While it would be rash to express any opinion on these figures without knowing something more of the conditions, on the surface it is difficult to understand how the saving of £156 is to be effected, even with the engine thrown in. We make this observation in the interests of all concerned.

THE SOCIETY OF ENGINEERS.—At the next ordinary meeting of this society, to be held on Monday, 7th November, at 7:30 p.m., at the Westminster Town Hall, a paper will be read on "Primary Batteries for Illuminating Purposes," by Mr. Perry F. Nursey, past president, of which the following is a synopsis:—"Introduction. A wide field open for primary batteries. Their principles and history outlined. Descriptions of batteries for special purposes, and batteries for general lighting, including those of Holmes and Burke, Ross, Coad,

Digitized by Google

Lalande, Skrivanow, Upward, Pollak, Newton, D'Humy, and Friedlaender; and the 'Regent,' the 'Union,' and the 'Eclipse' batteries. Conclusions." Several of these batteries will be exhibited at the meeting.

THE INSTITUTION OF CIVIL ENGINEERS.—The ordinary meetings of the Institute of Civil Engineers will be resumed on Tuesday, the 8th November, and be continued weekly till the end of May. At the opening of the session Mr. Geo. B. Bruce (president) will deliver his address. On subsequent occasions the following papers, amongst others, are to be read with a view to discussion:—"Accidents in Mines," Part II., by Sir Frederick Abel, C.B., F.R.S.; "Electrical Tramways: the Bessbrook and Newry Tramway," by Dr. E. Hopkinson, M.A.; "Manganese in its Application to Metallurgy," and "Some Novel Properties of Iron and Manganese," by R. A. Hadfield. The supplemental meetings of students have been appointed to commence on Friday, November 18th, and to take place at nearly fortnightly intervals.

TELEPHONES FOR SICK ROOMS.—A correspondent of a daily journal mentions a recent application of telephones to and from the bed rooms of scarlet fever patients. A telephone from the sick room to the rest of the house is a great comfort in any case, but in all cases of infectious disease is an immense alleviation of the patient's lot. The cost of putting one up is comparatively trifling, and the gain to the prisoner is important. Before it is up his bed room is his world, and a very thinly populated world too; for often enough the only members of society he sees are the doctor and the nurse, and the dreary hours pass by monotonous and solitary. After the telephone is fixed, adds the enthusiastic correspondent, "he can talk to his friends, he can listen to a novel, he can play chess or cards, he has a score of diversions; and all this without the slightest risk of infection."

RUMOURS.—We are more or less credibly informed that preparations are now being made for the invasion of the City of London by alternating currents on a prodigious scale. At Deptford (another account says at Millwall) several acres of ground have already been cleared for the erection of the (ex)-central station. Five marine engines, each of 4,000 horse-power (another account insists, however, that there are only four engines, each of 5,000 horse-power), are to provide motive power. An unknown number of dynamos, each with 40-feet armatures, are to supply current at 10,000 volts. Perhaps we had better say no more for the present.—It is stated that the Water Primary Battery Company have secured on a long lease a site in York-street, Westminster, "where a large central station will be erected for lighting by electricity the mansions and buildings in Victoria street, Westminster, and in Pimlico." Seeing that the neighbourhood of Victoria-street is the quarter wherein electricians and engineers most do congregate, this resolve of the W. P. B. Co. should perhaps be regarded as proof of simple good faith.

SECONDARY BATTERIES AT BRUSSELS.—We learn from the *Bulletin Internationale de l'Electricité* that the trials of the Tamine accumulator which have been carried on for some months by the Société Industrielle d'Electricité have not resulted satisfactorily, and their manufacture has been suspended. It will be remembered that the Tamine is a zinc-lead cell, and it appears that the difference in the density of the mixed solution of lead and zinc salt has a tendency to put a stop to the chemical action in the upper part of the plates. The evil then grows at an accelerated pace. There was also discovered a tendency to run down on open circuit, which is, we believe, a discouraging feature of most of the lead-zinc combinations hitherto tried. The next cell on the list appears to be the "Tudor," which is at present in the stage of great expectations. The Tudor cell is said to have had a long trial at Luxembourg, and to have given excellent results, particularly as regards durability. It is of the Planté type, and appears to rely upon a special form of grid for its peculiar merits. The Tudor cell is now to be tried in Brussels.

BIRMINGHAM.—An installation which has just been completed by Messrs. Chamberlain and Hookham in this city affords an undeniable instance of an economical victory over coal-gas. Such instances are not so plentiful that we can afford to overlook any one. The installation in question has been erected for the Linde British Refrigerating and Ice Company, who occupy premises in the basement of the Birmingham Fish Market, so that artificial light is required all day long. But in addition to this the Linde Company carry on their work night and day continuously, so that every lamp has the chance of making about 8,600 hours per annum. This alone would probably bring down the relative cost of electricity compared with gas at, say, 2s. 6d., to something like level terms, but in addition to this it happened that motive power was already available, so that friction clutches and countershaft alone remained to be provided. Messrs. Chamberlain and Hookham assure us that the total annual charge will not, under these circumstances, exceed *one-fourth* that for gas at 2s. 2d. per 1,000 cubic feet. The installation is not a large one. There are two Hookham dynamos, one for 12 55-volt 16 c.-p. lamps, and the other for 30 55-volt c.-p. lamps. At present only 25 lamps are hung.

BRUCE'S BALLOON SIGNALS IN BELGIUM.—On the 26th ult., some trials of Mr. E. Bruce's system of transmitting military signals at night took place at Antwerp, before General Pontus, the Belgian War Minister, and several distinguished officers of the Belgian army. Our readers will probably recollect that this arrangement (which has been adopted in our own army) consists merely of putting some incandescent lamps inside a small balloon which is allowed to float at a moderate height, and then flashing signals by means of a Morse key with carbon contacts. The system is so simple and practically certain in its operation that it scarcely needs any preliminary trial, and we need hardly say that the rehearsal at Antwerp gave perfect satisfaction to all concerned. The signals were easily read at a distance of 3,000 metres, but observers were also stationed on the cathedral tower at Mechlin, and on the church at Wilrysch—distant about twenty miles. Their reports had not been published, but owing to the fact that the balloon only attained a height of 100 metres, it was not thought probable that the signals could have been seen so far. We have little doubt that the arrangement will become common in the European armies. We may add that the batteries used on this occasion were supplied by the Electrical Power Storage Company.

ELECTRIC LOCOMOTIVES VERSUS AUTOMATIC CARS.—With regard to recent criticisms on the Elieson tram-car system, it is only fair to call attention to the fact, stated (or implied) in our article on October 21st, that the system does not rely exclusively upon the use of separate locomotives. It is true that the gearing requires a good deal of space, and probably the floor of an automatic car fitted with Elieson gear would have to be raised higher from the ground than an ordinary car. That is a point upon which we have no information at hand, but we do know that the Elieson Company proposed to stock the Manor Park line with automatic cars, and did not intend to build any more separate locomotives. We have

Digitized by Google

always held that the separate locomotive is out of place on a tram line, and this view is, we know, shared both by the Elieson Company and by the Electric Traction Syndicate. But the fact is that in the preliminary stage the Elieson Company had no option. The tramway company, naturally and reasonably enough, said in effect, "Here are our cars; can you take them just as they are and draw them by electricity?" To this question it is evident that the only possibility of affirmative reply arises from the use of separate locomotives. If it were a question of stocking a new line we suppose that there would hardly be two opinions as to the proper choice.

PROF. GEORGE FORBES IN AMERICA.—As many of our readers will be aware, Prof. Forbes left England for America shortly after the close of the British Association meeting, mainly in order to exhibit his new meter at the American Institute of Electrical Engineers. The American public, however, takes so genuine and intelligent an interest in the practical applications of science that the advent of Prof. Forbes and his meter has created a stir far beyond the bounds of the purely electrical community. The Sunday issue of the New York *Sun* (October 16th) devotes over a column to the subject, and gives a rough woodcut of the instrument. The article has, in American fashion, three headlines, in type of various sizes, as follows:—"To Measure Electricity. An English Scientist Sets Up A Practical Meter. It Will Tell How Much Lightning Flows Over A Wire, And Tell It Not Only To The Producer But To The Consumer." After this introduction follows a sensible and well-written article describing the apparatus in detail. After the innings which American inventors have had on this side it should be a source of gratification, not only to Prof. Forbes's personal friends, but the entire British race, if the new meter comes into universal use in the States. In another column will be found a condensed report of the discussion which followed the reading of the paper at the Institute of Electrical Engineers.

CLOSING OF THE NEWCASTLE EXHIBITION.—The attendance on the closing day amounted to 54,716, raising the number of visitors for the season to over 2,092,000. Throughout the whole run of the Exhibition no short-circuit or other accident involving risk of fire occurred in the building in connection with the electric light, and the only occasion upon which any considerable number of lamps were extinguished occurred about a fortnight before the closing day, and this was an accident for which the electricians were in no way responsible. A small piece of packing blew out of one of the flange joints of the main steam pipe about 6 p.m., and the engineer in charge thought it advisable to shut off steam at the boiler until the joint was repaired. This involved the extinction of the principal lamps in the four main courts for nearly an hour; but the lights in the western annexe, one of the largest courts in the Exhibition, measuring 650ft. in length, all the lights in the central and north gardens and verandahs, the picture galleries and dining rooms, the offices, and main entrance, as well as a number of small lamps about the courts, remained unaffected, so that there was everywhere sufficient light to prevent accidents; and the portions of the Exhibition which remained fully lighted were far more than sufficient to accommodate the visitors. By about 7 p.m. everything had resumed its normal condition, and no one was inconvenienced by the accident except a jury, who were anxious to finish their work before closing time.

FOR "SAFETY" SAKE.—We feel that we owe some amends to a correspondent signing himself "Safety," whose letter of inquiry we recently inserted in our correspondence columns, and to whom as yet no reply has been given. "Safety" inquired whether it was true "in lighting a theatre by electric light" that "any time a wire was broken" an arc light would be set up between the broken ends which might easily cause a fire, and if so what precautions are of avail to prevent this. The *possibility* of a fire arising in this way is undeniable, but the *probability* of such an event is, or may easily be made, extremely remote. "Safety" will easily understand that this is the case if he will consider (1) that by far the greatest portion of the conductors employed in wiring buildings are composed of stranded cables made up of many smaller wires, which are therefore extremely difficult to break. In many cases the whole of the wiring is done with this kind of cable, and there is no reason why this should not always be the rule. (2) These cables are nearly all enclosed in special pipes or mouldings, and should never be required to support any strain, so that except in the event either of a structural accident to the building or of malicious design, the breaking of a cable is an almost impossible event. (3) Lastly, supposing such a thing to have occurred, even then an arc would not be set up, unless the severed ends of the cable remained quite close together, which is unlikely considering the force required to effect the break. "Safety" may rest assured that a network of gas pipes, with its threefold possibility of fire, poison, and explosion, is decidedly a more dangerous addition to a theatre than a network of electric conductors.

THEATRE LIGHTING.—The stars in their courses fight unweariedly for the suppression of gas in the theatres of London. Within seven days we have had two more hair-breadth escapes. The Canterbury Music Hall was actually on fire, and but for the gratifying fact that the behaviour both of the staff and of the audience was beyond all praise, a catastrophe would undoubtedly have ensued. At the Lyceum, the other evening, Capt. Shean (the second in command of the Metropolitan Fire Brigade) actually saw a piece of paper fall from the gallery, take fire in a naked gas flame and flutter into an empty box. We take it to be just as important (and far less harrowing) that the public attention should be fixed on incidents of this character as upon such horrors as the burning of the Opéra Comique or of the theatre at Exeter. That a certain amount of good has been effected by the recent agitation is undeniable, but very much remains yet to be done. In France the subject continues to receive great attention, and on the 21st ult. M. de Hérédia, the Minister of Public Works, attended a meeting of the Société des Ingénieurs in order to listen to several short descriptive papers on the use of electric light in theatres, followed by a debate on the whole question. During the proceedings M. Vernes, chief engineer of the Continental Edison Company, called particular attention to the fact that, owing to the high temperature of the gas flame, the cordage and draperies of the upper portion of the stage of a theatre lit by gas were always found to be in an almost desiccated condition, and this, he had no doubt, would account for the extraordinary speed of such conflagrations. M. Vernes then went on to deal with the precautions necessary to be taken in the wiring and machine rooms, and was followed with great attention by the engineers and their distinguished guest.

LONG RUNS OF ENGINES AND DYNAMOS.—A Mr. H. M. Kinsley, proprietor of a restaurant in Chicago, states that an Edison 250-light dynamo, driven by an Armington-Sims engine in his possession, started running on July 24th at 9 a.m., and stopped on September 25th at 10:30 a.m., making a run of 63 days 1½ hours, or 1,513½ hours. At 330 revolutions per minute this is equal to 29,967,300 revolutions, and at the end of this time a little keying up was all that was required. The load is said to have varied between 75 and 275 lamps.

Digitized by Google

This is not, however, the longest continuous run on record. So far as we are aware that honour still belongs to the pair of Edison machines which in 1884 ran without stopping for 97 days in the Post Office at Boston. It would be interesting to know what type of engines was employed in the latter instance. Third on the list comes, we believe, a Kapp machine, which was reported last year to have run continuously for 26 days and nights on board H.M.S. "Devastation." Machines running on board ship are certainly handicapped heavily, so that this probably runs the Chicago performance very closely for second place. Then there is the Edison-Hopkinson machine, built by Mather and Platt, which was shown at the Inventions Exhibiton, and had done a 14 days' continuous run. We believe that the E. P. S. Co. on one occasion ran a Brush machine continuously for about six weeks. Finally, we may mention a run of nearly 17 days made in New York in 1883—again by an Edison machine. Doubtless there are many machines whose performances have not been chronicled in type which have done as well, and there are makers who would be prepared to guarantee to beat the record if it were worth while. In fact, as soon as a machine has attained its maximum temperature throughout a prolonged run does not really involve any additional strain.

Experiments on the Rate of Propagation of an Electric Current.—Upon the telegraph line between Bâle and Lucerne M. Hagerbach has recently carried out some experiments to determine the rate of propagation of the current. His method is extremely beautiful and ingenious, and is based upon the well-known experiment of Lissajous, in which a ray of light is reflected successively from the prongs of two tuning forks which vibrate in planes at right angles. If the forks are precisely in tune, then the resultant motion of the reflected ray describes upon the screen either a right line, an ellipse, or a circle according to the relative *phase* of the vibrations of the two forks. In M. Hagerbach's experiment the vibration of the forks is maintained by an electro-magnet make-and-break in the usual manner. The electro-magnets are placed in circuit with a battery, and a switch is arranged so that the telegraph line can be thrown into circuit between the two magnet coils. The line being first cut out of circuit it is found that the spot of light describes a narrow ellipse, showing that the phase of the second tuning fork is slightly behind that of the first owing to the retardation in the coils of the magnet. But as soon as the whole length of the line is thrown into circuit the ellipse widens out, and thus visibly demonstrates the increase of retardation. From measurements of the figures described the time of retardation can be calculated. M. Hagerbach made the experiments over various lengths of line, but the actual values obtained are not of much value owing to the very complex nature of the problem. The retardation varies directly with the square of the resistance, but it depends also upon the permittance, inductance, and impedance of the circuit, and of these terms no record is given. The results showed, however, considerable departure from the simple ratios of the squares of the resistance of different lengths of the line. A full account of the experiments will be found in *Wiedemann's Annalen*, Vol. XXIX., p. 377.

A Remarkable Improvement in Link Leather Belting. Several of the electric lighting stations in Boston are now employing a link leather belting made by Mr. C. L. Ireson of that city which is said to yield results of a remarkable character. The improvement consists in making the belt in two or more longitudinal sections, which are hinged together by their edges; the hinges are about the same length as the other links, but the joints of these links run the opposite way—that is, parallel to the length of the belt. By this means a flanged pulley is unnecessary, and the belt fits itself over a round or cone-faced pulley almost in the same way as a plain belt. For the smaller sizes only two sections—that is, one longitudinal hinge—are used; but as the width of the belt is increased the number of sections is also augmented. In this way, moreover, full advantage may be taken of the great weight of link leather belting, and it becomes possible to run with a very slack belt. At the recent meeting of the American Electric Light Association at Boston a 3in. belt of this description was employed to transmit power from a 6 horse-power electric motor to a countershaft, from which two 4in. plain belts drove some other machines. In this case (we quote the New York *Electrical World*) "the link belt was so slack on the following side that in running from a 5in. pulley to a 24in. pulley, which were set about eight feet apart on the centres, there was a sag of about ten inches from the straight line which would have joined the highest points in the crown surface of the pulleys, the sag of the belt bringing the lower part of it within four inches of the hauling side of the belt. In consequence of this sag the lap of the belt on the small pulley was more than a semi-circumference, while with ordinary belting this lap would have been somewhere from a quarter to a third of the circumference. As a result of this there was no slip, and a much narrower belt could be used than if frictional contact between the belt and the pulley had been required to be made by the width of the belt instead of by the length of the same."

Electric Lighting Accidents in America.—An American journal reports that Frederick Nelson, aged 21 years, a lineman employed by the Brush Company of Philadelphia, was recently killed whilst connecting wires running into No. 511, South-street, Philadelphia, with the main current. Mr. D. Law, general superintendent of the company, who examined the wires immediately after the accident, said the main wire had apparently been cut, and the young man had evidently been attempting to splice the "cut-out" so as to continue the current. The "cut-out," the superintendent continued, is a piece of wire several feet long, the ends of which are spliced to the main wire when a connection is to be made. It acts as a safeguard when the main wire is cut between its ends, the current being at once diverted into the "cut-out." There is a systematic way of proceeding about making connections, and the linemen are called together monthly and expressly cautioned not to follow any other method. The "cut-out" is first put in place, and then the main wire may be cut with comparatively little danger. In this case, however, he said, it seems as if the main wire had first been cut, and an attempt to splice the "cut-out" made afterwards. Nelson had been employed by the company since April, and was regarded as a capable workman.—An accident of a peculiarly distressing character is also reported to have occurred to a young girl who was being taken over a central lighting station. It appears that the end of a loose wire connected with a machine of high potential became entangled with her dress, and in some way made metallic connection with her body in the neighbourhood of the spine. She received a severe shock, and for upwards of four days the poor girl remained completely paralysed, notwithstanding the care with which the doctors attended to her case. Then she recovered the use of her limbs; but at the same time, though there was no perceptible loss of appetite, she began to lose flesh, and continued wasting away until she is now described as a mere skeleton. Her hair, moreover, which had turned completely white, has fallen off, and her skin is wrinkled and withered like that of an aged woman.

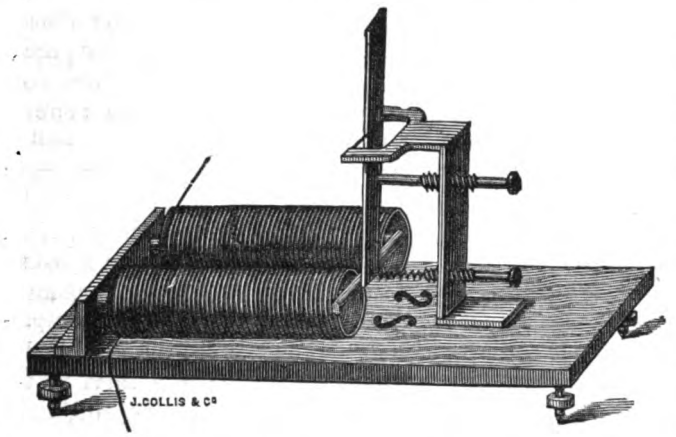
THE RISE AND PROGRESS OF TELEPHONY IN THE UNITED KINGDOM.

(Continued from page 475.)

We reproduce from our last chapter the engraving of the most interesting and important of the Reis receivers. Our knowledge of this instrument is solely derived from a paper "On the Reproduction of Tones by Means of Electro-Galvanism,"



by V. Legat, Inspector of the Royal Prussian Telegraphs in Cassel. This paper appeared in 1862, in the *Journal* of the Austro-German Telegraph Society (Vol. IX., p. 125); a full translation is given in Prof. Thompson's book, and from this we take the following description of the apparatus:—

"The receiver consists of an electro-magnet, which reposes upon a sounding box, and whose wire coils are respectively connected with the metallic conductor, and with the earth or metallic return conductor.

"Opposite the electro-magnet stands an armature, which is connected with a lever, which is as long as possible, but light and broad.

"The lever is fastened, pendulum-wise, to a support, and its movements are regulated by a screw and a spring.

"In order to improve the action of the apparatus, this receiver can be placed in one focus of an elliptically arched cavity of corresponding size, in which case, then, the ear of him who is listening to the reproduced tones may be placed at the second focus of this cavity.

"The action of the two apparatuses here described is the following:—

"In a condition of rest the galvanic circuit is closed.

"In the transmitting apparatus, by speaking (singing, or leading into it the tones of an instrument) into the tube, in consequence of the condensation and rarefaction of the air present in this tube, there will be evoked a motion of the membrane closing the tube at its narrow end, corresponding to this condensation or rarefaction. The lever follows the motion of the membrane, and opens and closes the galvanic circuit, so that by each condensation of the air in the tube an opening, and at each rarefaction a closing of the galvanic circuit ensues.

"In consequence of this process the electro-magnet of the receiver will be demagnetised and magnetised correspondingly with the condensations and rarefactions of the mass of air in the tube [the mouthpiece of the transmitter], and the armature belonging to the magnet will be set into vibrations similar to those of the membrane in the transmitting apparatus. The plank, connected with the armature, conveys these similar vibrations to the air surrounding the apparatus, which finally transmits to the ear of the listener the tones thus produced.

"We are not, therefore, dealing here with a propagation of sound through the electric current, but only with a transference to another place of the tones that have been produced, by a like cause being brought into play at this second place, and a like effect produced.

"Here, however, it must not be overlooked that the preceding apparatus reproduces, indeed, the original vibrations in equal number, but that equal strength in the reproduced vibrations has not yet been attained, and the production of these is reserved for a completion of the apparatus.

"One consequence of this temporary incompleteness of the apparatus is that the slighter differences of the original vibrations are more difficult to discern; that is to say, the vowel appears more or less indistinct, the more so since each tone is dependent, not only on the number of vibrations of the medium, but also on the condensation or rarefaction of the same.

"By this it is also explained that, in the practical investigations heretofore carried on, chords, melodies, &c., were transmitted with marvellous fidelity; while single words uttered as in reading, speaking, and the like, were perceptible more indistinctly. Nevertheless, here also the inflexions of the voice, the modulations of interrogation, exclamation, wonder, command, &c., attained distinct expression.

"There remains no doubt that before expecting a practical utilisation with serviceable results (praktische Verwerthung mit Nutzen), that which has been here spoken of will require still considerable improvement, and in particular mechanical science must complete the apparatus to be used; yet I am convinced by repeated practical experiments that the prosecution of the subject here explained is of the highest theoretical interest, and that our intelligent century will not miss the practical utilisation (Verwerthung) of it."

It will be interesting at this point to mention that in his "Rede Lecture" for 1878, Prof. J. Clerk Maxwell referred to the Reis telephone in the following terms:—

"If the pitch of a sound were the only quality which we are able to distinguish, the problem of telephony would have received its complete solution in the instrument of Reis. But the human ear is so constructed, and we ourselves are so trained by continual practice, that we recognise distinctions in sound of a far more subtle character than that of pitch, and these finer distinctions have become so much more important for the purposes of human intercourse than the musical distinction of pitch that many persons can detect the slightest variation in the pronunciation of a word who are comparatively indifferent to the variations of a melody."

Clerk Maxwell evidently shared the impression of Reis himself, that no effect could be obtained unless the platinum contacts underwent complete separation—in other words, that the transmission must be by make-and-break. This was in 1878. We are now better prepared to understand, or at any rate to accept, the fact that provided the adjustment was such that a sound of given volume only stirred without completely breaking the contact, the characteristic harmonies might be faithfully reproduced, and speech thus become possible. This is what the Reis transmitter can do, provided always that it be spoken to in a sufficiently gentle tone. On this point Prof. Sylvanus Thompson in his evidence at the trial in question spoke as follows:—"Reis's transmitter was intended by the inventor to work as a make-and-break contact instrument; and the inventor expected it to produce articulate speech by this action. As a matter of fact Reis did obtain articulate sounds, *but this was when the instrument worked in a manner which it was not intended it should.*" Even when spoken to in a gentle voice the transmission is usually very imperfect, continual interruption occurring as a "break" takes place.

Not much, however, was made of the transmitter on either side. Edison had already disclaimed one of his instruments in which a pair of platinum contacts were employed, although there was this important difference—the two contacts were permanently connected through a high-resistance shunt. Although the Reis telephone was mentioned amongst the particulars of objection to the Edison patent, and was referred to in evidence, the point was not pressed by the defendant's counsel, and was not alluded to by the learned judge in his decision. The fact seems to be that notwithstanding, on the one hand, it has been denied that the Reis transmitter will transmit articulate speech at all, it has not, so far as we are aware, ever been asserted, on the other hand, that the instrument is capable of fulfilling the conditions of practical telephony.

(To be continued.)

ELECTRIC MOTORS FOR THE SPANISH NAVY.

Messrs. Immisch and Co. have just completed a very interesting electrical plant for the Spanish Navy. The plant includes two 30 horse-power, three 4 horse-power, and one ½ horse-power motors. The machines were all built to the specification of the Spanish Naval Commissioners, and were tested in the presence of three of their representatives. The tests showed that the contractors had fully discharged the conditions of the specification. The annexed tables give the figures obtained from one of the 30 horse-power motors. The horse-power given out was measured by a Prony brake. The diameter of the pulley was 24in., and the face 17in.; the length of the arm of the brake was 63in. The brake was balanced so that it was only necessary to read the actual weight on the arm. The formula used was

$$\text{Horse-power} = \frac{2\pi l n w}{33000},$$

where l = length of brake arm in feet, n = revs. per minute, w = weight on arm in lbs. Putting $l = 63$in., we have

$$\text{Horse-power} = \cdot 001\, n\, w$$

which is a very convenient form for calculation.

Speed.	Weight in lbs.	Volts.	Amps.	H.-P.	E.-H.-P.	Efficiency.
660	45¼	500	49	29·8	33	90
680	45¼	500	48	29·5	32·2	91
675	45¼	500	49	29·5	33	89

[The figures given are those observed and recorded by the Spanish Naval Commissioners.]

The resistance of the armature was ·47 ohm, and that of the field ·355. These resistances were taken when the machine had acquired the normal temperature for full output. The volts lost over the resistance of the machine were $49 \times \cdot 825 = 40 \cdot 5$ volts. Therefore the theoretical possible efficiency of conversion was $\frac{459 \cdot 5}{500} = 92$ per cent. nearly. The actual efficiency obtained averaged 90 per cent., allowing about 2 per cent. loss for mechanical friction, Foucault currents, &c.

The 30 horse-power motors weigh 17cwt. Each machine is fitted with a resistance frame, divided into three sections for starting. The reducing and make-and-break switches are so arranged that all the resistance must be put into the circuit before *breaking*; hence it is impossible to start without first running through the resistance. A large supplementary switch, with an extra long break, is also provided for use in conjunction with the reducing switch, or separately, in case of emergency. It is intended to run the motors from accumulators, and provision has been made to couple the cells in single series or two parallels, thus giving full or half speed on the motor shaft. The commutating switch used for this purpose is locked by the reducing switch in such a manner that it is only possible to change the coupling of the cells after the circuit is broken on the reducing switch. This obviates the risk of short-circuiting the accumulators. The direction of motion is changed by reversing the current in the armature. A sufficiently substantial switch is provided for this purpose. The brushes are of the Immisch, balanced, tangent type. The machines run very smoothly, and are practically sparkless.

LITERATURE.

Electricity for Public Schools and Colleges. By W. LARDEN, M.A. (London: Longmans, Green and Co. 1887.)

"In this course the writer aims," says the preface, "at giving a sound though elementary knowledge of electricity." Upon the whole, we have come to the conclusion that—so far as the purpose can be accomplished by mere book work—there is no treatise at present in the field better adapted to fulfil the intention of the author than this of Mr. Larden. We shall have something presently to say in criticism of the author's general method, but first let us give an intelligible reason for the somewhat sweeping verdict which we have pronounced. It is impossible to go through these pages without being struck with the firm grasp which the author at every point displays, not merely of the subject in hand at the moment, but also of the exact amount of information which he has hitherto imparted, and the precise degree of knowledge—so much and no more—which the pupil is at each stage supposed to have attained. Now, this is one of the points upon which so many otherwise excellent text books are sadly at fault. It is undeniable that one of the most serious difficulties which is encountered by elementary students of physical science arises from the fact that there does not and cannot possibly exist any natural and inevitable order of discourse upon the phenomena of the universe. In Nature there is neither before nor after, all things co-exist. It is but a truism to say that the complete elucidation of a single one of the so-called "elementary" phenomena would in general require such a knowledge of molecular physics as is yet utterly—perhaps hopelessly—beyond our reach. Our method of separating and labelling phenomena as "electrical," "chemical," "thermal," "optical," &c., is highly convenient, no doubt; but, after all, it is only a rough-and-ready means of getting over a preliminary difficulty, and of penetrating the realms of the unknown from various different directions. A valid conception of the principles of no one science can be obtained without more or less acquaintance with the progress which has been made along many convergent paths.

The task of the teacher of science is therefore to select what to his judgment appears—in the then stage of scientific progress—the best, and safest, and easiest course along which to conduct his pupil. The selection must of necessity be arbitrary; and cannot therefore possibly be proof against criticism at every point. But when once the choice is made what is of vital importance is that the writer should clearly realise in his own mind the ins and outs of the devious paths along which he undertakes to guide the student. In this essential qualification Mr. Larden appears to us to attain an unusual standard of excellence. The sciences with which electricity is most closely in touch are those of Chemistry, Mechanics, and Heat. The author demands at the outset an acquaintance with as much chemical knowledge as may be gleaned from the elementary text books of Roscoe and others of similar grade. In Mechanics he had intended, he says, to include such propositions as are necessary where and when they are first required. Considerations of space, however, forbade this plan, and for the most part he has been content "to indicate merely the exact amount of knowledge required." The latter remark would in general also apply to his treatment of the theory of heat.

An equal care to discriminate the supposed condition of mind in the student is manifested in the treatment of the various divisions and sub-divisions of the main subject. Cross references to various parts of the work continually occur, and when the exigencies of the treatment adopted require them such references are carried forward as well as backward.

As to the substance of the lessons, our space will not permit us to enter into detailed criticism, because we have yet to pick a quarrel with the author upon a question of more general interest. We must therefore be content to observe that the work is brought well up to date, is in general both lucid and accurate, and contains just about as much mathematics as is indispensable to a proper understanding of the theory without burdening the pages with unnecessary symbols. The calculus is not introduced. There is a salutary and refreshing absence of many (though not quite all) of the hackneyed diagrams and illustrations which have done duty in most text books for the last twenty years, and a corresponding introduction of numerous figures, some of which we now meet with for the first time in a volume of this character—though as regards the instruments shown, most, if not all, have at various times appeared in our own columns. Mr. Larden's book should, in brief, be accorded a place in the literature of the more purely theoretical treatment of electricity beside that of Ayrton's "Practical Electricity," or of Stewart and Gee's

Digitized by Google

recent work on the more experimental side; and would serve as an introduction to Cunnyngham's "Theory of Electricity."

Having said all this we have now to express an opinion that Mr. Larden's whole course of treatment is fundamentally wrong. It is the very excellence of the book which makes us think it worth our while to express this emphatic opinion. But let us explain. We have said that every systematic course in physical science must necessarily rest upon an arbitrary decision as to the order of treatment, and it can be little more than a matter of opinion as to which of all the possible schemes is the best. Our opinion is that the scheme selected by Mr. Larden is not, on the whole, the best possible, though in many of the details it is doubtless a good deal better than certain others which might be named. It would, perhaps, be not impossible to defend the thesis that of all possible orders the historical is the worst. Without going as far as this, we cannot fail to recognise that the writers of text books have in general allowed themselves to be far too much under the domination of the historical order of discovery. Mr. Larden, as we cordially recognise, has to a considerable extent emancipated himself from this groove, and indeed in the preface he expressly disclaims any idea of conveying a notion at the same time of the principles of the science and of its chronology; but having gone so far we have only to regret that he did not go further. Let us—in part to economise space, and in part to offer a constructive rather than a merely destructive criticism—content ourselves with the bald statement of Mr. Larden's order of treatment, and then briefly set forth what we conceive to be a more consecutive and more generally appropriate scheme. Our author's main divisions are in order as follows:—Elementary Magnetism, the Simpler Phenomena of Electro-Statics, Introductory Chapter on Potential, Condensers, Induction Machines, Atmospheric Electricity, Electric Currents and their Phenomena, Ohm's and Joule's Laws, Thermo-Electricity, Magnetic Actions of Currents, Magnetic Fields, Solenoids and Electro-Magnets, Electro-Magnetic Induction, Rhumkorff's Coil, Dynamos, and other practical applications. We have omitted to put down several of the minor divisions. A consideration of this scheme will necessarily reveal that there are numerous cases of *non sequitur*—"faults" in the geological sense. Now we take it that it must be a criterion of the relative excellence of rival schemes that the one which is able to cover the most ground in consecutive order is, other things being equal, the better.

The following would be our own scheme; but in making the comparison we do not fail to recollect that Mr. Larden has written his book with all its detail, while we are only laying down the first broad outlines of an ideal. The reader will not fail to bear this in mind, although we shall still expect him to decide that of the two schemes our own is decidedly the more promising.

We take it that both in magnetism and electricity, as well as in electro-statics and electro-dynamics, the fundamental conception with which the pupil has to become familiar is that of the circuit. Now, there can be no two questions that the most simple, visible, and tangible circuit is discovered in the properties of the voltaic cell. Here, then, we should begin. It is tempting, no doubt, to rub a glass rod and show the student the strange and almost startling powers it has acquired. It is calculated, no doubt, to enlist his attention to promise some further elucidation of the mysteries of the familiar compass needle, and of the red-painted horseshoe magnet. But if we assume—as Mr. Larden most properly does—an elementary acquaintance with chemistry, then surely it is more useful to take a piece of copper and of zinc in dilute acid, and to discourse at once of the nature and properties of the voltaic current. We must not now stay to work out details, but it is obvious that the action of solenoids would lead directly to the discussion of electro-magnetism, where two paths would diverge, the one to the phenomena of the permanent magnet, and the other to that of dynamic induction. The conception of the magnetic circuit could probably be introduced quite early with advantage. Electro-statics, admittedly the most difficult branch of any, might, perhaps—we speak here with some additional diffidence—be approached with advantage through the phenomena of the Rhumkorff coil. But, however this may be, we feel on sure ground when we insist upon the necessity of introducing at an early stage of this branch of the subject the conception of the electro-static circuit. This is but a bare skeleton of a scheme, yet we venture to think it capable of not unsatisfactory development.

But even though Mr. Larden has not written upon our plan, his work is still among the best of its kind with which we are at present acquainted.

On a Surf-Bound Coast; or, Cable-Laying in the African Tropics. By ARCHER P. CROUCH, B.A. (London: Sampson Low.)

Our first feeling on opening a book of this description is one of surprise that hardly anything of the kind has been ever attempted before. The opportunities afforded by cable-laying expeditions, and the leisure at the command of those who have to work the cables when they are laid, are so pregnant with foreign travels and adventures, that one would have thought the telegraph profession might have found a market for its experiences long before now. Mr. Crouch has begun well, and we hope that his example may be imitated by other hands. We may hope, too, that they will take warning by some of the blemishes which disfigure what in the main is a very readable and entertaining book. The diary style is about the worst that could be adopted for a continuous narrative; the disguise of all the names, both of ships and men, detracts from the veracity of the story, and is, so far as we can judge, a quite unnecessary piece of reticence. Lastly, the author commenced his diary apparently with no fixed object, and to the very end of it does not seem clear as to whether he intends it as a book of travel or a record of chit-chat. To Mr. Crouch himself, and to others of his profession who may aspire to follow in his footsteps, the best advice we can give is, before putting his notes into book form, to ask himself the question, For whom am I writing? Lovers of books relating to travels in strange lands are extremely numerous, and works of that description are the more saleable for being written in a lively vein with occasional strokes of jocularity. Mr. Crouch unfortunately tells us far too little about the towns and peoples on the West Coast of Africa, but far too much of the doings and conversations of the people on board his ship. Only three months of the voyage are included in this volume. With judicious pruning in one direction and grafting in another it might have covered the whole six months, and been very much improved by the process. Mr. Crouch is a keen observer of men and things, and he possesses both the powers of description and the gift of narration so needful for a work of this kind. His account of the landing in a surf boat (p. 235) is an admirable sample of the former, only there is too little of it; whilst of the latter the examples are far too numerous, many of the incidents and dialogues having no interest whatever except for the parties engaged in them. Apart from these faults, however, "On a Surf-Bound Coast" is a capital book of its kind, and the reader will find on almost every page something to attract and amuse him.

AN IMPROVED EARTH PLATE.—Prof. Dorn, in the *Electrotech. Zeits.* for October, proposes a form of earth plate which should be valuable to all observers of earth currents, if, as is claimed for it, it reduces polarisation to a minimum. It consists of a flat open box, made of wood or cement, and coated inside with asphalte. This is placed at the bottom of a hole in the ground. An amalgamated zinc plate lies flat in the box, and an insulated wire leads from it to the surface. Care must, of course, be taken that the joint is well covered, so that nothing but zinc is in contact with soil. An earthenware pipe stands on the zinc and rises to the surface. The box is then tightly rammed with clay, soaked with concentrated zinc sulphate solution, and the hole filled up. Solid sulphate is dropped down the tube and solution poured after it. A little fresh sulphate from time to time will keep the plate in order.

SOUTH OF ENGLAND TELEPHONE COMPANY.—The Directors of this company have declared a dividend of 6 per cent. per annum on the Preference Shares for the half-year ended 31st October.

INDEX TO VOLUME XIX.

With this number a Supplement is issued (Gratis), containing the Index to Volume XIX. This Supplement should be received with every copy of the paper. Complaints of non-receipt should be at once forwarded to the Publisher.

NOTICE.

We beg to notify that all correspondence and contributions intended for this Journal should be in future addressed to THE ELECTRICIAN, 1, Salisbury-court, Fleet-street, E.C., instead of to Mr. C. H. W. Biggs, whose connection with it has ceased. We deem it right to add that no other change whatever has occurred or is contemplated in the proprietorship or management of this Journal.

SCIENCE AND BUSINESS.

It was far from our intention to raise any dispute about the functions of Science and Trade when we took up the scheme of an Electrical Engineering Association. But some people are hard to please. In deference to the scientific branch of the profession we disclaimed all idea of invading its province, and this with an emphasis which was intended to be reassuring, but which has been interpreted as abandoning the proper functions of scientific and technical journalism in order to "take the commercial affairs of our readers under protection." This is an attitude which fills our contemporary, *Engineering*, with amazement, and serves as a text for a good deal of tall talk about science and a vast amount of disparagement about business. For our part we have no hesitation in confessing that the protection of "our readers" is regarded in this office as one of the duties we owe to those readers, whether their interests be scientific or commercial. That this view of their duty is shared by the majority of our electrical and engineering contemporaries is confessed by the journal which so loftily takes them to task. The highly moral isolation in which *Engineering* has entrenched itself does not very much concern us; but we take leave to remark that it does concern the "readers" of that technical and scientific organ, and that it will find the reckoning with them not so simple a matter as writing a derisive article about them.

Except to remove any remaining misapprehensions with regard to the proposed Association of Electrical Engineers, we should not have referred to the line taken up by our esteemed contemporary, whose freedom of criticism and action we do not in the least dispute. But we must demur to the designation TRADES UNION as applied to this scheme, and still more to the suggestion that it is intended to dissever itself altogether from "the principles of science or the practical application of them." The latter is impossible; we have distinctly said so more than once, and the phrase "except indirectly" in the passage quoted from our leader in support of the opposite contention indicates that we have never lost sight of the fact that any association of the kind under discussion must be directed on scientific principles, and must receive its inspiration primarily from scientific teaching. Indeed, it is the absence of this steadying element in the profession of electrical engineering, including, as it now does, the tinker and tailor, if not the soldier and sailor, that operates to its discredit and tends to bring it to ruin. Existing professional and trade associations have been formed, partly, at least, to exclude incompetent intruders who have no business to be there—an object surely in complete harmony with those superlatively scientific and technical aims which our contemporary has propounded. It is admitted that the programme we have sketched out is "desirable and laudable;" but the affairs embraced in it, says *Engineering*, "do not come within our province ..... and nothing is further from our intention than to put ourselves in the false position of supplying an initiative to a body of men who are perfectly capable of acting for themselves."

In justification of this remarkable deliverance our contemporary disclaims "all pretensions to deal with the commercial aspects of engineering." It is our turn now to be amazed. We cast our eyes over the pages which contain this notable utterance to see whether they differ from the pages familiar to us in times past. They literally bristle with "commercial aspects," and, to repeat our own words, "except indirectly, they have nothing whatever to do" with science. And then, how about the advertisements? But we will not pursue the examination. It is really too painful; and we may dismiss it with the remark that if the readers of a journal can be judged by the matter given them to read, then the journal referred to is as much beholden to, as much dependent upon, and as much devoted to the commercial affairs of its readers as every one of its contemporaries. The chief difference appears to be that in respect to the scheme promoted with more or less warmth by its comrades, *Engineering* has chosen to adopt a tone of superiority which not only quarrels with the bread and the butter, but sneers at the bakers and dairymen. For besides accusing them of trying to form a trade ring, Electrical Engineers are described as being selfish and thoroughly distrustful of each other; and with very good reason apparently, as they are generally engaged in the "process of mutual throat cutting." If this were a faithful description of the electrical engineering profession it would

Digitized by Google

be pretty clear that it is not composed of men quite competent to take care of themselves. But in that case the services of their recognised organs in the Press are all the more needed; and we have no right to stand aside, letting the trade or profession, or whatever we please to call it, go to the dogs under the pretence of having no concern with it. Whatever comes of the proposed Association we declare our conviction that we are serving the interests both of science and of its practical application by assisting those engaged in promoting the latter; and if they are convinced, as indeed they appear to be, that the present unsatisfactory condition of the trade might be set in order by associated action, we shall do what we can to help them.

It is useless, however, to deny that in the article on which we have been commenting there are indications of a genuine alarm for the safety of existing institutions, such as that of the Civil Engineers and the Society of Telegraph-Engineers. We are warned that the last named society "will be quite equal to meeting the occasion if the new Association should develop a scientific aspect;" and no doubt our friends will take note of the warning, which, though oddly worded, is seriously meant. We do not share these apprehensions; we rather think the electrical engineers could meet very profitably without developing any aspect hurtful to the feelings of that or any other society. But if we did feel any misgivings on this point we should at once say to the society threatened that it had better be quick in "meeting the occasion." We strongly deprecate the formation of any society that would run counter to the welfare of established institutions. What we say, and what our friends feel, is that no existing organisation provides at all for the wants which electrical engineering, considered as a business profession, has developed. That, we venture to assert, must be admitted; and, once admitted, we see no reason why those wants should remain unsatisfied because other societies of a kindred order cannot satisfy them. If they think they can, and will try, why, let them set about it at once. Meanwhile steps are being taken to ascertain what is the feeling of our correspondents on this as well as on other points connected with the idea of a new association.

THE COWLES ELECTRIC FURNACE AND THE ALUMINIUM ALLOYS.

The gigantic dynamo machine built for the Cowles Electric Smelting and Aluminium Company by Messrs. R. E. Crompton and Co. is this week being erected at the company's works at Stoke-on-Trent. This machine is considerably larger than the Brush "Colossus," which has been at work since September, 1886, at Lockport (U.S.). The Brush machine absorbes 350 horse-power, while the Crompton machine has a guaranteed minimum capacity of 300,000 watts (5,000 amperes and 60 volts), and will require 500 horse-power. We shall hope shortly to place before our readers full details of this machine, and of the Cowles process as carried out at Stoke-on-Trent; meanwhile, the following extract from the report of the Committee of the Franklin Institute which was appointed to examine the works at Lockport, U.S., will be of interest:—

The essential and valuable novelty of the process is the ingenious application of the intense heat, obtained by the passage of a powerful current of electricity through a conductor of great resistance, to the reduction in the presence of carbon of the most refractory ores, some of which have hitherto resisted all similar attempts at reduction. In this process, the crushed ores are mixed with fine charcoal, and, for the production of alloys, with fragments of copper, or some other metal or metals from the part of the circuit offering the greatest resistance to the electric current, and subjected therefore to the highest temperature. The heat developed is so great that nearly all oxides are decomposed, and charcoal is changed to graphite. . . The process is applicable to all kinds of ores, but particularly to those unreducible by other means.

The value of aluminium bronzes and other alloys containing aluminium is so well known that we shall only say a few words concerning them. Full and interesting details may be found in metallurgical works, chemical dictionaries, engineering, and special text-books. All authorities unite in their phrase, and predict an extensive use for them. Their high price alone has prevented their general employment in the past, but in spite of their costliness the demand is not inconsiderable. The usefulness of the aluminium bronzes is due to their great hardness, tensile strength, and stiffness.

They are also ductile, malleable at high temperature, and elastic. They resist the action of the air, moisture, and many other chemical agents, far better than brass or bronze. The lustre of silver or gold may be given to them. Under some conditions silver and gold tarnish much more readily than the aluminium bronzes. They may be cast, rolled, or forged. The castings are of great strength and homogeneous; repeated meltings only slightly decrease their tensile strength, without causing any loss of weight. Large castings may be made with care; small castings are readily secured.

The Lockport Works will have a capacity of six thousand pounds daily, and the company expects to profitably sell the 10 per cent. aluminium bronze for less than forty cents per pound—in fact, Mr. Cowles intimates in the paper that the price may be as low as fifteen cents per pound.

The Cowles Electric Smelting and Aluminium Company promises to furnish within a year pure aluminium for fifty or sixty cents per pound. If raw material of sufficient purity can be obtained cheaply, this can probably be done. . . The members of the committee have, moreover, no doubt of the ultimate success in the production of pure aluminium at a moderate cost.

The scientific possibilities of the invention must not be overlooked. The intense heat of the electric current is so completely under the control of the operator, and the other conditions are so favourable, that not the slightest doubt should exist of speedy and valuable additions to our knowledge of metallurgical and chemical processes. Already aluminium alloys of iron, silver, tin, cobalt, and nickel have been prepared. Silicon bronze, potassium, sodium, magnesium, calcium, chronium, and titanium, as well as aluminium, have been obtained in a free state. An apparently new oxide of silicon awaits supply. The opportunities for the formation of new and important alloys seem unlimited, and it is not improbable that some of our *elements* may be resolved into different kinds of matter.

Much speculation is, however, out of place in a report of this kind, but the committee is of opinion that the Messrs. Cowles and their associates deserve the highest commendation for their inventions, furnishing as they do a distinctly new and important metallurgical process that will render possible the cheap production of useful alloys, compounds, and metals, and giving to science a valuable aid in research.

THE RIES ELECTRIC TRACTION-INCREASING APPARATUS FOR RAILWAYS.

Mr. Ries' apparatus and method of increasing tractive power on rail or tramways will be found fully described on page 391 of the present volume. It appears to us that this system is likely, perhaps in the near future, to obtain a position of recognised importance amongst the applications of electricity. At the Exhibition of the American Institute of Electric Engineers a working model of the system is now being shown. We take the following from the New York *Electrical World*:—

One of the most recent as well as one of the most valuable and interesting of the electrical exhibits is that of Messrs. Ries and Henderson. This exhibit is at present in charge of Mr. Ries himself, and attracts a great deal of attention, even from non-scientific visitors, who view with mingled wonder and delight the novel spectacle of a model railway car ascending, without the slightest difficulty, a grade upon which an expert tobogganist might fear to entrust himself for a downward trip. The outfit comprises two model railway tracks, each capable of being elevated at one end to various heights, with a motor-car for each track, and a dial for registering the amount of pull or tractive force exerted by the cars under different conditions. The Ries electric traction-increasing system embodies a new application of electricity, one that gives promise of a wide and extensive field of usefulness, especially in connection with steam and electric railways, and is particularly valuable at the present time in view of the possible influence it may bring to bear upon the successful development and introduction of electric street railways. It is well known that one of the greatest obstacles that have been encountered in applying motors, whether steam, compressed air, electrical or any other kind, to the operation of street railways has been the difficulty of securing sufficient adhesion between the driving wheels and track in wet or slippery weather, and especially so on railways having steep grades. In this respect cable and horse cars have heretofore had an advantage because of the application of the tractive force independent of the car itself, and, therefore, independent of the amount of friction or adhesion between the wheels and track rails. As the ordinary street car rails are necessarily level with the street surface, they do not permit of the same tractive effect as the elevated rails commonly used on steam and suburban railways, and it has therefore been possible to employ independent motors successfully only on roads having grades of less than 6 per cent., or a rise of 6ft. in a length of 100. In view of the fact that many street railway lines have grades of from 10 to 15 per cent., it does seem self-evident that some method of artificially increasing the frictional adhesion of the

Digitized by Google

driving wheels must be employed before electricity can be successfully utilised as a motive power for operating street cars in our crowded cities on steep grades. In one of the model cars exhibited by Messrs. Ries and Henderson this increased adhesion is produced in a very simple and inexpensive manner by means of magnetising helices or coils of wire on each axle, through which a current of electricity is passed whenever this additional tractive force is desired, as, for example, when starting a heavy load, or on going up an incline, or in case of a slippery track. So effective is this method that the car shown readily ascends a grade of 40 per cent., or 2,083ft. to the mile, by virtue of the magnetism induced in the wheels, and the peculiar arrangement of the magnetic circuit. The rolling motion of the wheels is not appreciably affected, and the amount of current required for producing this magnetising effect is extremely small and insignificant when compared with the results obtained. The second model above referred to represents the operation as applied to steam railways. Instead of magnetism, a different arrangement is employed in which the molecular action of an electric current of large volume is caused to increase the frictional adhesion between the locomotive driving wheels and the track. This property of the electric current was observed and its commercial importance pointed out by Mr. Ries, in a paper read by him before the American Association for the Advancement of Science, at the recent meeting in this city. In this system the locomotive is preferably provided with a small alternating machine, the current from which passes through a "converter" to give it the required volume, and this current is then led to the forward pair of driving wheels, which are insulated from the body of the locomotive. From these wheels the current enters the track and flows back to its source by way of the rear pair of driving wheels, the arrangement being such that only that portion of rails which lies between the two pairs of wheels is in the electric circuit. Consequently no danger from shock by coming in contact with the rails exists. The tractive effect is due to the molecular change and heat produced by the current at the point of contact between the wheels and rails, which causes a very decided increase in the coefficient of friction between the two surfaces, and prevents slipping or skidding of the wheels. The amount of current passing can be regulated by the engineer to suit different conditions of track and load, and it is claimed that an increase of from 50 to 100 per cent. in the tractive power of existing locomotives can be obtained with a very economical expenditure of current.

BARDONNAUT'S "SOURDINES."

The adjoining figures illustrate several forms of the "sourdine ressort" (or spring muffler), introduced by M. Bardonnaut, for checking the noise caused by the vibration of telegraph wires. This is the arrangement referred to by Mr. Charles Bright in his letter on page 520. No further explanation will be required. These devices, though obviously of only limited application, may at

FIG. 1

FIG. 2.

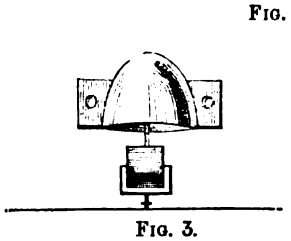

FIG. 3.

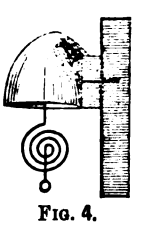

FIG. 4.

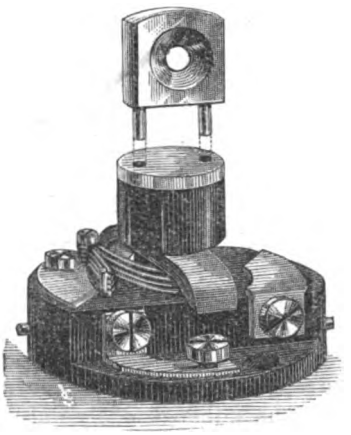
times prove useful. We believe that some use has been made of them by the United Telephone Company, though at one time they preferred to insert a short piece of chain in the line where the sound caused annoyance. The arrangement shown in Fig. 2, which is most like that proposed by Mr. Caws, differs, however, from the latter in the fact that it requires a joint on each side of the insulator. Figs. 3 and 4 are front and side views respectively of a bracket arrangement.

NEW WOODHOUSE AND RAWSON SWITCH.

The adjoining figure represents a switch of useful pattern which has recently been introduced by the Woodhouse and Rawson Manufacturing Company. The switch is represented in the figure with the case removed. The base is of slate, and a powerful throw-off spring with good rubbing contacts are provided. The thumb-



screw is made detachable, so that the switch cannot easily be tampered with by any unauthorised person.

ON THE THEORY OF ELECTRIC ENDOSMOSE AND ALLIED PHENOMENA, AND ON THE EXISTENCE OF A COEFFICIENT IN CONTACT WITH A SOLID.*

BY PROF. LAMB, F.R.S.

The paper deals with the laws governing the electric transport of ions in conducting liquids through the cells of porous vessels or along capillary tubes and other related phenomena which have been investigated experimentally by Profs. Wiedemann and Quincke, and explained by the latter writer on the assumption of the contact difference of potential between the fluid and its solid boundaries. This explanation has been developed mathematically by Von Helmholtz. Applying the known laws of motion to viscous fluids he found that the calculated results so far as they depend on quantities which admit a measurement are in satisfactory agreement with the experiments, and that the values which it is necessary to assign to the contact difference above spoken of are in all cases comparable with the E.M.F. of a Daniell cell. Incidentally, also, he arrives at the conclusion that in the cases considered there is no slipping of the fluid over the surfaces of the solid with which it is in contact. In the present paper a slightly different view is taken, and it is assumed that a certain finite (though possibly very minute) amount of slipping takes place, and that it forms an essential feature in the phenomena. The various cases considered by Von Helmholtz are treated on this assumption, and in some respects extended. In all cases the results differ from those obtained by Von Helmholtz by a factor l/d; where l is a linear magnitude measure the "slip" namely $B = u/l$, and d denotes the distance between the plates of the air condenser, whose capacity per unit area is the same as that of the opposed surfaces of solid and fluid. For example, by comparison with Wiedemann's experiments Von Helmholtz infers that for certain solutions of $CuSO_4$ in the pores of a clay vessel $E/D = 1{\cdot}77$, where D is the E.M.F. of a Daniell cell. On the hypothesis adopted in the present paper the inference would be that $\frac{E}{D} - \frac{l}{d} = 1{\cdot}77$. This involves two unknown ratios. No such definite conclusion can be drawn, but it is evident that the phenomena are consistent even with very small values of E/D, provided l

* Abstract of a paper read before the British Association Meeting at Manchester September, 1887.

Digitized by Google

be a sufficient multiple of D and *d*. Since D is a quantity of molecular order of magnitude (comparable with 10^{-8} centimetres) the value of *l* may still be so minute as to render the effects of slipping quite insensible in such experiments as those of Poisenille. They come to be of importance in the cases at present under consideration only in consequence of the relatively great forces due to the fall of potential along the course of the current, which act on the outer electrified layer of fluid and attract it over the surface of the solid.

CORRESPONDENCE.

SPRINGS ON TELEGRAPH WIRES.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I think that if some of your correspondents who are advocating the use of springs for telegraph wires had had some experience in the erection of heavy overhouse cables, they would find that they are not necessary. Nothing at reasonable cost will provide against such damage from snow and wind as was experienced in the snowstorm of last December; but for all ordinary strains the elasticity of good copper and iron is sufficient, if not destroyed by the process of "killing."

For example, if two No. 7/14 strand iron wires be erected parallel with one another in a span of 250 feet, and one loaded with a cable which is heavy enough to increase the dip by 5 feet in the centre of the span, it will recover its normal position upon the removal of the load, and become again parallel with the other wire. That this elasticity is not destroyed by age is shown by another case, in which a cable suspension wire (which had been erected some years), upon the removal of its cable, rose and put eleven wires which crossed it above in contact. This elasticity, moreover, prevents the alteration of the dip with temperature in proportion to the known rates of expansion and contraction of the metals.

In a span of 250 feet the difference in the dip between winter and summer is but a few inches, if the wire be set up without "killing" and well within the limits of its elasticity.—Yours, &c.,

F. HIGGINS.

17, Cornhill, E.C., Oct. 31st, 1887.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: Let any of your readers stretch a cotton thread across the table, say between two chair backs, and then let a heavy knife, such as a carving knife, fall across that thread. If the thread is tight enough the falling knife will cut it asunder. It is easy to make the thread so tight that it will be cut, or so slack that it will not be cut.

Now let your readers join to each end of the thread a short length of elastic, and secure the latter to the chairs, straining the thread to the same minimum tightness as enabled the falling knife to cut it before. Will the same knife cut it now? No. Why not? The reason is self-evident. The elastic, by increasing the extensibility of the thread, enables it to yield and save itself.

The thread is the telegraph wire, the elastics are the regulator springs, the knife is the falling tree branch.

By increasing the extensibility of the catenary, the regulators render it correspondingly more secure against catenary loads generally, whether sudden or continual, whether loads of snow, ice, hailstorms, windstorms, falling trees, or any or all of these combined.

The increase of extensibility afforded by the particular regulator which I recommend enables the line wire with regulators to withstand *double the load* (sudden or continual) that the same line wire without regulators can bear.

This increase of extensibility virtually doubles the strength of the line without doubling its actual strength. The breaking stress of the 100lb. copper wire, for example, will be 330lb. in any case, whether with or without regulators. But that breaking stress in the wires as now hung would be caused by half the load that would cause the same wires to break if regulators were furnished.

If Mr. Preece were to urge that doubling the virtual strength of the wires, though a decided gain, is not a sufficient gain to justify even the extremely moderate cost of the regulators, his contention would be intelligible, though not sustainable. But he writes as though the storm stress on a tube of frozen snow would be the same stress with as without regulators (which is a great mistake), and he says the springs "will not be of *any service whatever* in preventing the wire from breaking." To sustain his proposition is to controvert laws of force, as your instructed readers will see for themselves.

Mr. Preece remarks that my invention is not novel. According to King Solomon, nothing under the sun is novel. But it was quite novel to me when I invented it, and evidently novel to Mr. Preece when he heard it from the lips of Sir F. Bramwell on the 4th Sept. at Manchester; else Mr. Preece would not have urged at first blush that it necessitated cutting the wire at every post.

I agree with Mr. Charles Bright, jun., that it is not improbable such an idea may have occurred to telegraph engineers before; but it is noteworthy that since this discussion was commenced at Manchester by Sir F. Bramwell no telegraph engineer has claimed the invention. I can only surmise that if any engineer conceived the idea during what I may call the "iron age" of telegraphy, he would soon find, as I found, and as Prof. Perry has since stated, that the springs were too clumsy and costly to be generally admissible. We are now at the beginning of the "copper age," when the same drawbacks of clumsiness and costliness no longer confront the inventor.

I did not aim at stopping the humming of the wires, but Mr. Bright is right in pointing out that the automatic grippers will have that effect. And I stated the same thing in reply to a query in the *English Mechanic* last week.

Mr. Preece is right in stating that my regulators would cause more snow to accumulate, for each spring would carry a snowtuft; but he fails to show how this could possibly "magnify the evil." He cannot mean the evil of excessive stress; for as to the *mechanical* condition of the catenary, it is plain that the snow wreaths on and about the insulators produce (whether greater or smaller) no appreciable stress. It is the snow on the *span*, not the snow on and about the *posts*, which adds to the stress so powerfully during gales. And it is evident that the wire with regulators would gather on its span no more snow than the wire without regulators.

Then as to the *electrical* conditions during a snow covering. These are somewhat *improved* by the use of the regulators; for, by the present system, the wires, being fast bound to the insulators, are necessarily enveloped in those wreaths of snow which not only collect on each insulator, but which frequently also bridge across the space between insulators, and thus tend to conduct cross currents between the line wires. But, as your readers will have noticed, the "bow" (as Mr. Bright calls it), or slack line wire between the small extra insulators, of my patent is bent *sideways* and *upwards*, for the express purpose, mainly, of making the line wire avoid the vertical plane of the springs and insulators, so that the line wire may follow a path quite *above* and *clear of* the snow wreaths.

Of course snowstorms will occur of such severity as occasionally to neutralise more or less this particular improvement; but in the greater number of snowstorms the line wire; with regulators will be more free of snow about the insulators than the line wires as at present hung.

My invention is designed to render the lines twice as secure as now against snowstorms and falling trees, also to entirely prevent chafing and leakage at insulators. Does Mr. Preece regard snowstorms, falling trees, chafing and leakage as "imaginary troubles"?

I may take this opportunity to point out to telegraph engineers that the spring regulator has all the advantages without the disadvantages of a *shackle*. Also the handling by the linesmen of the brittle-skinned copper wire is rendered less rude and not less rapid by my method of erection.

TABLE OF DIPS, STRESSES, EXPANSION AND STRETCH OF A 100 YARDS SPAN OF COPPER LINE WIRE AT VARYING TEMPERATURES.

Coefficient of Expansion = ·00001 per deg. Fahr.
Modulus of Elasticity = 14,500,000lbs. per inch of sectional area.
Minimum Factor of Safety = 4.

Column A refers to copper wire weighing 100lb. per mile, *i.e*, ·0189391b. per foot, having a sectional area = ·00493in., and diameter = ·079in. Breaking stress = 330lb. Elastic limit = 165lb.

Column B refers to ditto 150lb. per mile, *i.e.*, ·028409lb. per foot, having sectional area = ·00735in., and diameter = ·0967in. Breaking stress = 495lb. Elastic limit = 247·5lb.

Columns marked * show what the dips, stresses, and catenary lengths would be if the wires were absolutely inelastic. These * columns agree very nearly with Mr. Preece's tables, reckoning from 22deg. Fahr. as datum. If * stress items (which relate to 100lb. wire) be multiplied by 1·5 they will give * stresses for 150lb. wire.

It is with regret I find myself in apparent conflict with Mr. Preece; but I cannot, in justice to myself, or to mechanical science (the study and practice of which has more or less deeply engaged the best seventeen years of my life) accept even his *ipse dixit* as a true verdict.

I append a table of dips and stresses of copper wire catenaries at various temperatures, which, if Mr. Preece will compare with his own, will show him whether he has been justified in publicly declaring that I have not realised the conditions that determine the stability of a telegraph wire.—Yours, &c.,

FRANK CAWS.

Sunderland, 31st Oct., 1887.

THE PROPOSED ASSOCIATION OF ELECTRICAL ENGINEERS.

TO THE EDITOR OF THE ELECTRICIAN.

SIR: I am glad to see that the proposal to establish an Association of Electrical Engineers has been received with such evident favour by so many of the large firms both in London and the provinces. This practical unanimity of opinion not only shows the need of such an association, but also argues well for its success, if started. The electrical industry is comparatively new, and is growing so rapidly that it needs competent and careful watching to preserve it from disaster. Inexperience on the one hand, and unprincipled speculation on the other, have told their tale on the confidence of the public. A period of universal depression of trade has again handicapped the youthful industry, and an unhealthy trade competition has still further tended to depress it in this country. But yet electricity as a medium for lighting and the transmission of power is steadily gaining ground. The trade is to some extent recognised as a branch of mechanical engineering, but it is not yet sufficiently defined. There is too much tendency to look upon the electrical engineer as a scientist rather than a practical man, and I regret to say that oftentimes he is neither. Now the Society of Telegraph-Engineers does not pretend to regulate trade questions in any form; and its composition and general method of procedure make it eminently unsuited for such action. It is a scientific society. The association, however, would, I take it, be essentially representative of the firms and the men immediately engaged in heavy electrical engineering. Its proper functions would be the discussion of trade matters in their commercial bearing, and the exercising of a general supervision over the welfare of the industry. The association, moreover, speaking with the voice of the profession, would carry more weight than a few firms, and harsh legislation would no longer be possible. A method of determining the output of any dynamo or motor in general terms is very desirable, and would do much to reconcile the apparent disparity of prices now existing. This could only be done by such a representative association; indeed, the field for the usefulness of the proposed Association of Electrical Engineers is very large, and I hope to see it placed on a satisfactory basis very shortly. I shall be pleased to do all in my power to further its formation.—Yours, &c.,

ALBION T. SNELL.

24, Glycena-road, Lavender-hill, S.W.

DEAR SIR: Your suggestion of initiating a scheme for forming an Electric Light Convention in England is a good and seasonable one, which many members of the profession have at least talked about. The sooner it is got to work the better for all of us.—Yours truly,

HENRY M. SAYERS.

Dovedale, Moreton-in-Marsh.

Lord Edward S. Churchill presents his compliments to the editor, and having seen in *The Electrician* his suggestion for forming an Electric Light Convention, writes to say he would be willing to join.

Messrs. Paris and Scott, after expressing their approval of the movement, add:—"We think that it should concern itself more with the business aspect of electrical engineering, which need in no way mean an interference in one another's business, but solely to help with advice and practical knowledge any member in a difficulty."

ON ELECTRIC STREET CARS, WITH SPECIAL REFERENCE TO METHODS OF GEARING.*

BY A. RECKENZAUN, C.E.

(Concluded from page 523.)

FRICTION GEAR.

There is something quite fascinating in friction gear. It offers the advantages of simplicity, noiselessness, and theoretically a high efficiency; but as regards certainty of action and durability, it occupies a low position in the scale of appliances for the transmission of power. The late Prof. Fleeming Jenkin devised an apparatus a few years ago which he called "nest gearing," and of which great things were expected, and, indeed, it was regarded as the most perfect frictional gear ever invented.

Prof. Jenkin arranged several rollers within a ring; these rollers were in contact with a central friction wheel which was attached to the motor, and the outer ring was connected to the driven object. It is well known that in a pair of friction

* Paper read before the American Institute of Electrical Engineers, New York, Sept. 20th, 1887.

Digitized by Google

wheels when running together, the contact surfaces are exceedingly small, the pressure must be great, and consequently there is a rapid destruction of the said contact surfaces. Now, by placing a number of rollers within a ring, not only are the contacts multiplied, but there is a perfectly balanced pressure upon all the working parts. This kind of gearing, made of the best materials and of the finest workmanship, has been applied to the telpher line at Glynde. Its efficiency was tested and found to be somewhere near 95 per cent. In the case of telpher lines the motor and its attachments are well out of reach, suspended on tall posts, therefore dust and dirt can be absolutely excluded. The energy transmitted between the electric motor and the driving wheels averaged only 1·5 horse-power, and yet with all these advantages and the great care exercised in its construction and use, this gearing refused to act after a comparatively short space of time. The experiments were watched with intense interest by all who made mechanical science their profession, and especially by those who were seeking effective means of transmitting motion from electric motors. After a number of exhaustive tests, apparent improvements and modifications, the inventors of this nest gearing pronounced it a failure, and finally resorted to chains and cog-wheels. This fact, established after prolonged and most persistent efforts on the part of a number of the smartest mechanicians, should be a warning to all the advocates of friction gear for street car propulsion.

WORM GEARING.

Dissatisfied with the results of my early experiments I resolved to give worm gearing a trial. I collected all the data I could find in text books and from other people's experience. All the different authorities agreed on one point, and that was the efficiency, or rather the want of efficiency in worm gearing. According to various statements the *loss* with this mode of transmission was put down at from 33 to 75 per cent. This seemed to me a terrible waste of power; I was then, as now, engaged in the problem of utilising storage batteries for street car propulsion. Storage batteries were at that time in disrepute generally, and as for putting these cumbersome things upon a car, the very idea of it was ridiculed by conservative-minded men. Certain would-be experts published their views on this subject, and they endeavoured to prove mathematically that the battery could scarcely hold sufficient energy to propel its own weight, and that more than 50 per cent. of the power given by the charging dynamos was lost in the process of transformation. If they had known at the time that I proposed to introduce another energy-consuming apparatus in the form of worm gearing they would have declared me a lunatic. There were, however, quite a number of extenuating circumstances which encouraged me to pursue this question. I knew, from experience, that the storage battery, if properly constructed and used, could return more than 70 per cent. of the energy expended upon it; I knew also that a certain type of cell could propel several times its own weight at a speed greater than that of a horse car.

With regard to worm gearing, I found that this method of transmission was used for hoists and for actuating machine tools, and that in some cases it has been working for twenty years without requiring any expensive repairs. During all my researches I failed to discover any reliable data on the construction and use of a worm which had such a steep thread that the worm wheel could cause it to revolve. I did not come across any publication with figures to show the efficiency of gearing where the worm shaft revolved at a very high velocity whilst transmitting considerable power. Just at that time the valuable researches of Profs. Thurston and Kimball and Mr. Beauchamp Tower, on the subject of friction and lubrication, were published, and these revealed the fact that all the long established laws on friction were entirely wrong. The experiments of these scientists proved conclusively that the coefficient of friction varied with the velocity, and that it decreased up to certain limits, with an increase of speed between lubricated surfaces.

Furthermore, it has been demonstrated that the coefficient of friction between lubricated bearings is not ·1 or ·2, as so frequently stated in text books, but ·003 and less, and that even with moderately bad lubrication it amounted to only ·01. All these, and other considerations encouraged me in the belief that there is a fruitful field for further investigation, and I designed a set of worm gear of the following dimensions:—Steel worm, turned and polished, 6in. in diameter, 6in. long, treble thread of 2in. pitch; worm wheel of phosphor bronze, trimmed teeth, $15\frac{9}{22}$in. diameter, $3\frac{1}{2}$in. face, 24 teeth. Ratio of gear, 8 to 1. The worm was fitted to the spindle of an electric motor, and the worm wheel attached to the axle of a street car, which was supported on a frame with bearings to keep the wheels off the ground. When running empty, with the worm out of gear, the motor took 6 amperes of current, and when put in gear, but without any other load, 7·75 amperes were used to drive the apparatus at the same speed. Prony brakes were then applied to both the motor shaft and the car axle, and the power was measured on each at a given E.M.F., current and speed. The efficiency of the gearing was calculated by dividing the horse-power given off on the axle by that measured on the worm shaft, and we found that the useful effect increased with the speed, viz.: at 300 revolutions of the worm it gave 80 per cent.; at 520 revolutions, 81·1 per cent.; at 676 revolutions, 85 1 per cent., and finally at 770 revolutions, 87 per cent. These results were then compared with the electrical energy supplied to the motor in each experiment, and they were found to correspond very closely, after the usual electrical losses in the motor itself were deducted. The mechanical horse-power was thus checked by the electrical horse-power, and at last I applied the well-known formulæ for the efficiency of worm gear, which is given in every book on mechanical engineering—

$$E = \frac{\cot\theta}{\cot(\theta-\phi)} = \frac{1-\mu\frac{p}{2\pi r}}{1+\mu\frac{2\pi r}{p}},$$

where θ is the angle of the worm thread,
μ the coefficient of friction,
r the radius of the worm, and
ϕ the angle of repose between metal and metal;
E gives the efficiency of the pair.

If the coefficient of friction is taken at ·015, then the efficiency must be 87·5 per cent.

By means of the above tests and the formula we can find the coefficient of friction for the various speeds.

When this apparatus was attached to the car, I found that it required less current to propel it than it did previously with the chain gear, therefore I have always since used the worm gear. Mr. Holroyd Smith tried it recently on his cars, as already stated, and he told the meeting of the Society of Arts, in April last, that he "found it the most effective mode of transmitting the power from the motor spindle to the axle, taking all points into consideration."

With these remarks closes a short and incomplete chapter on gearing. There are other kinds of gearing which I have not touched upon. I cannot do better than to leave the subject in the able hands of members present, who, I hope, will supplement, criticise and amend the observations herein set forth, and thereby add to the general knowledge of one of the most important topics of the day. We are continually advancing; every hour marks a step forward in the direction of success. The grand general principles of the electrical transmission of energy are now well understood, but there are yet many other ways of adding to the sum of human knowledge, as for example in following up the details of construction, every one of which will add in some measure to the final triumph. Even by relating our mistakes and failures we serve a good purpose. "There are," said Prof. Silvanus Thompson, "half-forgotten observations, unconnected, unexplained, and often exceptional in character, every one of which has a significance of its own—residual phenomena, every one of which is, to the scientific man, of a value beyond price. He who investigates them patiently may find a clue to their meaning, and reap a rich reward from them. They are the finger-posts in the high road of discovery."

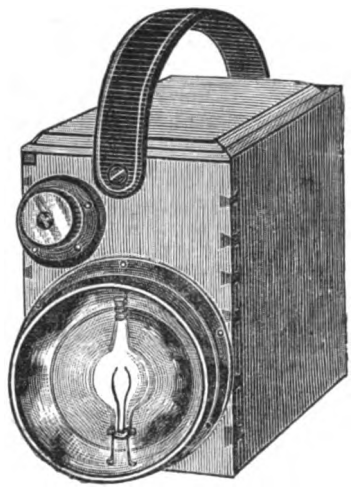
PITKIN'S PORTABLE LAMP.

We have been favoured with the following description of the Pitkin Portable Lamp, which is illustrated in the adjoining figure:—"These lamps are intended for use in coal mines and other places where explosions may be apprehended. They are the invention and manufacture of Mr. James Pitkin, of 56, Red Lion-street, Clerkenwell, who has spent some years in perfecting the details of their construction. Each lamp is of the form shown in the engraving, and weighs approximately 7lb.; they are, however, easily carried by means of a strong leather handle passing across the top from front to back. When the cells are fully charged the lamp, which is of four candle-power, will burn from twelve to eighteen hours, according to the degree of incandescence at which the lamp is burned. This can be conveniently regulated by means of a switch (shown upon the front of the box), which not only turns the light on and off, but by sliding over a platenoid wire of small diameter inserts more or less resistance in the circuit. The glow lamps are of the Swan type, and are suspended from above by means of a spiral spring, secured to a metal loop, fused into the glass globe forming the lamp. They are further held in position by means of the screws passing through the case and hooked to the under side, these also form the connection between the lamp and the cells. Each cell has eight small lead plates with a projecting edge forming a trough, and projections or pins of lead at regular distances,



which hold the storage material firmly to the surface of the plates. The whole arrangement is well designed and substantially made."

DISCUSSION ON PROF. FORBES'S METER AT THE AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS.

Prof. Forbes's current meter (which was described in these columns on September 23, page 421) has so far met with a very warm welcome in the United States. It will not be necessary to reproduce the paper which Prof. Forbes read before the American Institute of Electrical Engineers, which was practically the same as that already read before the British Association. But the following abstract of the discussion which ensued will be read with interest:—

Prof. FORBES: I would like to add one or two points about the instrument. In this instrument there is one part which I have not described to you, and perhaps before I describe it I ought to let you see it working. I am starting it with a current of 11 amperes. It takes a little time to get up its full speed and a little time to lose its full speed. I have shown this lighter form of wheel work, and I am making it even lighter than it is in the instrument which is being manufactured now. This instrument has a good deal of metal work, much more than in any of the instruments which I have been using before, and the mass of metal absorbs so much heat that it went on for a considerable time after the current was broken. Now this might suit the suppliers of electricity very well, but it would not, of course, suit the consumers, and one must defer to both sides. I do not want the meter to act in that way, and I find that by reducing the metal work as much as possible that difficulty is taken away. There is another point about this instrument which I have not shown you or spoken to you about. It is an arrangement which is attached to it for lifting up the mica vanes against a fixed stop above. I have moved the stop away at present. That lifts the mill wheel up against the stop and enables us to carry it about with safety. That is to say, I must make one reservation—there is fear of danger if it passes through the New York Custom House (laughter.) I brought in a lot of instruments, and after I saw a little of what the Custom House people were doing it sickened my heart so much that I let them lock the instrument up and put it in the public stores. I had worked six hours that morning like a slave, doing their bidding, and by the time it came to me I am sorry to say that many of the things were in a sad state. You will notice something hanging to this instrument (pointing to another). That was an extremely delicate spiral spring which was attached to one of these mill wheels, acting simply as an amperemeter, not arranged for registering the consumption, but measuring the rate at which the current is passing through the conductor. That instrument is quite disabled, and others too. I have also some diagrams here. Here are actual examples of some of the readings of these amperemeters, and I have sometimes taken them under different conditions. I have, for example, got the instrument with the clockwork in, and without the clockwork, showing the amount of friction, and I may tell you this, that it looks as if the wheelwork there would cause a considerable amount of friction which has to be got over. That friction is a mere nothing compared with the friction of the air which is circulating in these convection currents which are created. There are three frictions entering in the action of the instrument. First, there is the air friction in the currents of air, which is the chief source of friction; secondly, there is the friction of the jewelled cup on the point; and, lastly, there is the friction of the wheel work, which is far less than the friction of the jewelled cup upon the point. That is what one of these diagrams shows. Another one happens to show the effect when the apparatus for fixing the mill wheel is taken out. Another one may be of some interest to you. It was taken from the instrument when it was in an experimental stage. I varied the distance of the vanes from the conductors, and I used it at $\frac{1}{16}$, $\frac{2}{16}$, $\frac{3}{16}$, and $\frac{4}{16}$ of an inch. You might expect that the nearer it was to the conductor the greater the velocity would be of the given current. That is not so. It then creates friction by pulling the air from the surface of the wire when it was too near. Three-sixteenths of an inch was found to be the most suitable distance.

Dr. VANDER WEYDE: If you use a shade it would seem that when the apparatus is in operation a little while the air will be heated and the ascending force would diminish and become very small, at least when the air was considerably heated in the glass shade. To correct that nothing would be easier than to make an opening in the top of the glass shade to let the hot air out and keep the surrounding atmosphere more uniform. When the apparatus has been in operation for some time, so that the air becomes heated which surrounds it, the indications would become a great deal less. I wish to do justice to Prof. Forbes for the ingenuity of the apparatus, and the remark I made is only for the purpose of suggesting something which may make the apparatus more perfect.

Prof. FORBES: These are very suggestive remarks that come from Dr. Vander Weyde, and of course they occurred to me during the process of the experiments. There is one lesson that I have learned from this instrument, which is that you cannot calculate on what is going to happen with a convection current (applause). I have been as sure as possible, over and over again, when I was making a minute change in the instrument, that I knew as well as possible what it was going to do, and it never did it. Dr. Vander Weyde suggests that when the air at the top of the shade gets heated the instrument will go slower. The only answer that I can give to it is that it does not. It goes perfectly continuously, however many hours that I have it at work. He suggests that a hole should be made in the top to keep it cool. Nothing in the world will ever induce me to let a hole get into that mechanism any more than I would let the works of my watch be exposed to the open air to get dust into them. But it is quite unnecessary, for it goes any number of hours at a perfectly constant rate, even when the top gets hot. It is remarkable that the first person who has spoken at this discussion has raised the first objection which every person who has ever spoken to me about it has raised, and that is that its indications will depend upon the external temperature; that when the external temperature is high it will go quicker. This is the only one thing, however, in which practice does agree with theory in regard to convection currents. The theory of the thing is perfectly simple. The moving force is the *difference* of temperature between the conductor and the external air. It does not depend in the least on the *absolute* temperature of the place, it is only on the heat that is being generated in the conductor, and it is the difference of temperature created therein and the external air which gives you the moving force. It is a matter of indifference whether you start with a temperature of 30 or 100 degrees. As a matter of fact, the indications in a warm atmosphere and a cold atmosphere are identical. I may forestall the question that is going to be asked immediately, whether the barometer has any effect. I may say that I have not had the instrument under an air pump to test it, but I have tested it day after day, and I have seen no perceptible variations.

Dr. VANDER WEYDE: What becomes of the heat which is continually generated?

Prof. FORBES: It is radiated from the surface of the glass. A great deal collects at the top. A fixed temperature is arrived at of course, and the heat which is being created is all radiated from the surface of the glass.

Mr. FRANK L. POPE: The amount of heat which is generated by the action of the current is not very great at the most, and as it gradually collects in the top of the glass it is probable that before the hot air extends down far enough to affect the operation of the instrument the radiation has become great enough to carry away an equal amount of heat with that which is being generated, and the temperature from that on is stationary. The balance is brought about before the currents of air are affected sufficiently to affect the operation of the instrument.

Mr. MAILLOUX: There are some other points which I would like to bring forward. One point is about the friction of the apparatus. I would like to know whether the calibration of the apparatus does not depend for its constancy on the friction of the apparatus remaining constant as nearly as possible; and it also occurs to me to suggest that the friction of the apparatus may have a great deal to do with its sensitiveness as an

Digitized by Google

integrating instrument. In other words, if there is very little friction, it is quite likely that the inertia would be greater, and its momentum once obtained would tend to carry it over, so that if there were any abrupt changes in the current it would not so readily respond to them. So that if we were to draw a curve of variations of current it would in reality not follow that curve closely but only partially, introducing a quantity in the result which would be the analogue of self-induction with an ordinary apparatus. Now there is another point. We all know that in order to obtain heat from a conductor we must have a certain amount of resistance, and I would like to know whether the amount of resistance that has to be introduced in the wire (which I presume is iron from its appearance) is of material consequence, whether it would figure at all as n element of resistance of the whole circuit, and also whether, by virtue of its resistance or of its position, it would introduce any variation which has been called impedance in the circuit in consequence of self-induction or anything like that.

Prof. FORBES: The first question, as to the effect of the constancy of the friction—whether the speed of the instrument depends upon the constancy of the friction of the solid parts?—and the second question I had better take in connection with it, which is, whether that friction of the solid moving parts renders it less sensitive? First, we have to consider whether, after the lapse of months or years, when the mechanical parts of the instrument are not in such good order as when it was started, its readings will be as accurate as they were at the beginning? and in the second place, will it be so ready to start with a feeble current with the friction of the wheel work as without it? I have already said that the most important part of the friction in that apparatus is the air friction; but that is especially so in the case of a larger current. When the currents come up to the average strength or greater, the air friction is out of all comparison the greatest friction that we have in the instrument. At any time the friction of the wheel work, incredible as it seems to most people at first sight who are not accustomed to thinking much of the subject, is but a fraction of the friction of the jewelled cup upon the pivot. You must remember that the first wheel of the wheel work is rotated at only one-tenth of the speed of the mill wheel, and its weight is extremely light compared with the weight of the mill wheel, and the friction of the first wheel is therefore very slight indeed; and when you come to the second wheel, its speed of rotation is diminished tenfold, and its lightness is small compared with the mill wheel. I was told to expect this by a great friend of mine, whose name I ought always to mention in connection with this instrument, Mr. Augustus Stroh, who assisted Sir Charles Wheatstone in all of his celebrated inventions, and who has assisted me in all this work, and there is no man more capable of giving such assistance in the mechanical details of an instrument like this. I had intended to make a German pun, a thing I never did in my life before, and should have done so if it were not for the earnest objections of Mr. Stroh, and call this a Strohmeter (applause). That is the way that the friction of the apparatus comes in. It is very slight indeed compared with the air friction, except with very feeble currents indeed. The result always, then, has been that what I call the ratio of speed to current was constant whether the friction were a little more or a little less, but that it did not start quite so easily with extra friction, and I have no doubt that if the wheel work were to get seriously out of order, and we were to have very much more friction, it would not be so sensitive to a single lamp; but at higher speeds there would not be the slightest difference in the indications. For example, to show you how that works, I have two diagrams giving you the ratio of current to speed when different currents were passing through with the clockwork attached and without the clockwork attached. You would notice in these that with the clockwork attached it did not start with so small a current; but when the instrument was once in working order, from one and a-half amperes or so, or upwards, the two lines of ratio of speed to current were identical. Prof. Forbes then went on to say that experiment showed no difference in the behaviour of the instrument with alternating currents.

Mr. S. S. WHEELER: I would like to ask what the resistance of the coil used is?

Prof. FORBES: Nearly a tenth of an ohm.

Mr. SHELBOURNE: Now, in regard to the first question that was asked by Prof. Vander Weyde in respect to making a hole in the top, does it not appear that the apparent inaccuracy of the instrument in registering light currents and in getting its rate may be due to the generation of heat at the commencement, and that heat accumulating in the top of the instrument and heating the glass, it would arrive at a point where there is an equation between the generation of heat by the wire and the radiation from the outside of the glass? I simply suggest this, and I ask the professor whether he has ever tried in making instruments, instead of making the whole of the cover of glass, to put a dome of copper or some other conducting metal upon it, so that the air which rises and accumulates at the top may sooner reach that equation of radiation from the outside of the instrument with the generation of heat which operates the mill wheel?

Prof. FORBES: I really do not think that practically it is very important. Otherwise, I think the suggestion that was made very likely would be good—using a metal shade. Of course I have had numerous changes in shades. I have tried a shade which was nearly all metal. But I found this shade before you the best one I have used up to the present time. However, I think it is quite likely that the suggestion just made might be a good one—that a metal shade would be fully as good as the other—might be better, and might make it a little more sensitive perhaps. I think there may be a good deal in what you say.

Mr. WETZLER: I am a little interested in knowing whether any experiments have been made to determine the best angle and shape of the vanes of the mill wheel, and if the shape determined on there has been found to be the best.

Prof. FORBES: As to the angle, I have committed the grossest folly that a man with the experience I have had with this meter could commit—I have trusted theory. I have been positively certain that an angle of 45deg. must be the best. I am sorry Mr. Wetzler has drawn this confession from me, because it is really the only respect in which I have trusted to theory. As to the other points, the shape of the vanes has been the source of endless experiments. I made an enormous number of changes before I arrived at this shape, and even little details in the shape have come from experiment. I made hundreds of vanes in the experimental stage, and I am pretty sure that if that type of mill wheel is to be used the vanes are of the right shape.

Mr. WESTON: I do not know that I can say very much more than has already been said in regard to the instrument by Prof. Forbes. I think it is an extremely ingenious and beautiful instrument. There has been already a great deal of time and a large amount of money spent on electric meters for direct currents, and I can say with Prof. Forbes that I do not think we have had any current meter of any value whatever. The electro-chemical system in use by a very prominent company here was put out with a great deal of confidence with the results to be obtained from it. I think any one looking at the principles involved would condemn it from the start. You are to take a small fraction of the total current, and a very small fraction indeed, and pass it through an electrolytic cell, the character of which varies from time to time, so that the resistance is never fixed, and pass the bulk of the current around a resistance which is practically fixed. The change in the resistance of the metal would be but a small proportion of the change in the resistance of the electrolyte. Now in such an instance as that you are measuring a very small fraction of the current passing, and whatever error you have you are multiplying that error by that fraction. If you are measuring 1-1,000 you are multiplying your error by 1,000. Any one who has had much to do with electro-metallurgy knows that the cells are constantly changing; that to keep the deposit regular and uniform, to keep the resistance of the solution uniform, they must be constantly attended to. There is not an electroplater in the country who does not once in awhile go in and stir up his baths. Such an instrument is of no real value. We may therefore dismiss those instruments entirely from consideration, I think. A great deal of work has already been done on magnetic instruments; that is, instruments which depend upon the magnetic attraction of the current through a wire, or the current through a wire going around an iron coil. In those instruments we have all the defects which have been referred to as being possible to exist in this instrument here to-night, manifested a thousand times more, with numerous others that do not exist in this instrument at all. I can speak feelingly on the matter, because I have given a great deal of attention to it, and have thought once or twice I had something very good, and have been finally obliged to abandon it. Mr. Weston then described some experiments which he had made upon a meter of his own bearing a general resemblance to the Ferranti type. He had not, however, been satisfied with the result. The description is not intelligible without the aid of the sketches made on the blackboard. He continued: I do not know whether Prof. Forbes has done any work on the friction between a mass of metal revolving in mercury or not.

Prof. FORBES: I did a good deal of that at one time.

Mr. WESTON: If you did you will understand the difficulty. Nothing was accomplished. I may say, however, that it has already given rise to a very neat form of current instrument, in which, instead of having the disc rotate, it was fixed, a large index being brought out from the disc, in which case it was absolutely proportional to the number of lamps in circuit. For a station ammeter I do not know of anything that equals that to-day. It shows the current when there are 300 or 400 or 500 on, just as it shows one lamp by itself. Prof. Forbes has got here the simplest instrument that I think could be built. I do not see how you could improve it very much except in detail. The principles are correct, and I must congratulate him very highly indeed upon the success of the instrument.

Mr. RIES: After Prof. Vander Weyde's suggestion, which was the first one made this evening about the hole in the glass shade, it occurred to me that perhaps another principle besides those mentioned by Prof. Forbes might be utilised in the construction of a meter of this class. Prof. Forbes mentioned electro-chemical action, electro-magnetic action and caloric, or heat, as the basis for a measuring instrument of this kind. Now, if we could obviate the friction due to the revolution of these vanes in the air, and place them in a vacuum, like Crookes's radiometer, and instead of utilising the principle of heat use that of light to give motion to the vanes, I do not know whether that would not make a very delicate apparatus. It suggests a different direction in which to work. You might perhaps take these vanes and place them in a dark cell, surround them with a strip of platinum wire or carbon filament, and use the variations in light to change the number of revolutions per second, and that could be recorded by an apparatus similar to that used by Prof. Forbes. I simply offer that as a suggestion.

Mr. HOWELL: I was very much surprised to hear what Mr. Weston said. I am surprised that he does not know that there is a temperature correction in the Edison meter. The Edison meter has been in use industrially for five years, and I say without hesitation, and I am in a position to know the opinion of the practical men who are using the Edison meter, that they think a great deal more of it to-day than they did before, and the more they use it and the more they know of it the better they like it. There is one thing about that meter of Prof. Forbes which recommends it to me as the result of experience with instruments sent out for general use. There is one peculiarity about every American electrician, and that is, he has got to know what things are made of, and if you do not show him he will find out for himself. Now, that instrument shows itself. You can look at that and see what every part is, and you do not

Digitized by Google

need to take it apart. I have sent out a great many instruments. The first thing a man does with them is to pull them apart and see what they are made of. There is no necessity for pulling that instrument apart; you can see all about it. There is one thing I would like to ask Prof. Forbes, and that is the effect of lowering the shade? I see he has a shade there very much higher than the instrument apparently needs. I would like to know if that is necessary to allow for air circulation?

Prof. FORBES: Yes; it is more sensitive with a higher shade. That is about the limit. I have gone through dozens of shades to see what is the right size and shape, and that is the one I have fixed upon.

Mr. CROCKER: I ran roughly over the amount of heat that would be generated in Prof. Forbes's instrument, and it came so high that I should like to go over the figures now and see if they are right. He says the resistance is under a tenth of an ohm. Assuming it to be the tenth of an ohm, 20 amperes would give two volts drop, and two volts and 20 amperes would give us 40 watts; and 40 watts multiplied by 44·2 is about 1,760 foot-pounds, and 1,760 foot-pounds gives us two heat units, roughly. That is, two pounds of water will be heated one degree Fahr. in one minute by Prof. Forbes's resistance when it is working up to its full capacity of 20 amperes. Two pounds of water heated one degree is equivalent to eight pounds of air heated one degree. I believe the specific heat of air is a quarter that of water. That is my recollection; it may be wrong. There are eight pounds of air heated one degree Fahr. Now the contents of that shade there are approximately a quarter of a cubic foot. Therefore, the heat produced in that shade would be fifty times as much as it would be in one pound of air—8 times 50 is 400, therefore we have 400 degrees per minute. It is a very high figure. I cannot believe that it is right. But we know that the capacity of the amount of air in that shade for heat is very small, and we also know that the amount produced in a tenth of an ohm by 20 amperes of current is quite large. Therefore, perhaps that figure is approximately right.

Prof. FORBES: I think perhaps it would be better if I might be allowed to answer the question after it has been written out by the shorthand writer. It is rather difficult to follow the point where we went from water to air, and the larger quantities, and to see that the figures were right. But I do not see that the quantity of air that is heated, or the quantity of water that is heated, has anything to do with the question. I would suggest that the speaker, instead of taking that line, would simply multiply and find out how much energy is used in the meter when 20 lamps are burning, and divide one by the other and get the percentage. Settle upon the percentage more than which you are not going to use and you have it. I should think very much over 2 per cent. or so would be very undesirable to use. It some cases it might go up to 3 or 4 possibly, but I should think as a general rule you would find 2 per cent. as much as one would care to use. The question of the number of lamps you use simply depends on what amount of energy you care to use.

Mr. CROCKER: I did not mean the efficiency of the apparatus. I did not mean that Prof. Forbes's meter used up any considerable fraction of the current. I merely meant to bring forward as an interesting point exactly how much heat is produced in the meter in a given time, and to calculate it as well as I was able to with the figures I happened to have in my mind.

Prof. FORBES: Then I would point out that theoretically you have to take in another point, and that is that there is continual radiation going on, and that during constant running there is no addition to the heat contained in the instrument. It arrives at a constant condition when the heat generated in the wire is equivalent to the heat radiated from the surface of the glass. From numerous experiments, both in Sir William Thomson's laboratory, and also by Prof. Tait, we have got at the constant of emissivity, the rate of radiation, and it is very easy to go on with the calculation a step further than done just now, and calculate what is the temperature which would be reached when the emissivity or radiation from the surface is equal to the heat generated from the wire. The problem looked at simply as a theoretical problem of interest can actually be worked out by going a step further than the speaker has just stated.

Mr. WHEELER: What is the approximate temperature of the meter after running a few minutes?

Prof. FORBES: Running at its full it is 120 degrees, perhaps.

Mr. WHEELER: Even at that low temperature it must get enough higher than the surrounding air to radiate 2½ heat units.

Prof. FORBES closed the discussion as follows:—I feel that this discussion has been of great value to all of us. Very interesting points have been raised, and I have heard suggestions which have given me great interest indeed. Of course, in working at this instrument one started from theoretical notions, but one gave them up very soon, and one had all sorts of resources at one's hand to vary the forms of these curves, some of which I have already shown you. I should like to show you the curves which I got when I first made this instrument. The curve ought to be simply a horizontal line. One of the curves which I first got was of about this shape (resembling the letter U), and yet I had the greatest hope even when I got that. By two changes I was able to reduce the line down to a horizontal, and there were numerous other changes. In the course of working that instrument out I learned more about convection currents than I knew there was to learn, and really one has power now to handle them as one pleases. I have no more remarks to make, except that I thank every one here for the pleasant discussion we have had this evening. I think it has been very instructive, and I have felt throughout the same kind, cordial sympathy that was shown in England. I did not expect to find everyone ready to look upon it in the way in which Sir William Thomson did, without any sign of regret that it happened to be done by another. I thank everyone here most heartily for the cordial way in which they have received this stranger (applause).

On motion of Mr. PENDLETON, seconded by Mr. F. W. JONES, a vote of thanks was tendered to Prof. Forbes, and the meeting adjourned.

ON THE PHYSICAL PROPERTIES OF A NEARLY NON-MAGNETISABLE (MANGANESE) STEEL.*

By W. F. BARRETT, Professor of Experimental Physics, Royal College of Science for Ireland.

In the early part of 1884 Messrs. Hadfield and Co., steel founders, of Sheffield, exhibited at the Institute of Mechanical Engineers specimens of steel which they had recently manufactured containing from 10 to 13 per cent. of manganese. Up to that time it was, I believe, the general impression among mechanical engineers that a steel containing more than 1 per cent. of manganese was practically worthless. Nevertheless, Messrs. Hadfield showed that samples of their manganese steel had not only very great tenacity, but combined the valuable property of toughness with extreme hardness, and that it also made very good castings. But to the physicist the most interesting property of this steel is the fact, to which Mr. J. T. Bottomley drew attention in this section at Aberdeen in 1885, that manganese steel is almost wholly unmagnetisable. After submitting a bar of this steel to an enormous magnetising force Mr. Bottomley determined the intensity of magnetisation thereby produced in the steel, and he found a permanent magnetisation of only 0·013 C.-G.-S. units per gramme. Ordinary steel has a number varying from 40 to 60 and even up to 100 C.-G.-S. units per gramme—that is to say, ordinary steel is capable of an intensity of magnetisation from 3,000 to 7,700 times greater than that of manganese steel; or if the intensity of magnetisation in a specimen of ordinary steel of average quality be 100,000, that of manganese steel is only 20.

It is obvious from this that manganese steel is a remarkable body, possessing properties of interest and importance alike to the physicist and to the mechanical engineer; it was desirable, therefore, to submit the substance to further investigation. Mr. Bottomley was good enough to let me have his bar of manganese steel for this purpose, and Messrs. Hadfield, at my request, endeavoured to draw some of the steel into wire, so that I might measure its electric conductivity and modulus of elasticity by traction. The drawing of manganese steel proved of much difficulty, and Messrs. Rylands, the well-known wire drawers of Warrington, obliged me by making the attempt, but could not succeed. Eventually Messrs. Hadfield succeeded, after many ineffectual trials, and in writing to me thus described the process they adopted:—

"As exceedingly good bending tests had been obtained with bars of the same steel when heated to a yellow heat and plunged into cold water, it was thought worth while to attempt a similar experiment with the rolled rods before trying to draw it down into wire. The rods were coiled up, heated to a yellow heat over a smith's fire, and then plunged into cold water. It was then easily drawn into wire, starting with No. 7 gauge, when it was drawn to No. 9 with safety. This drawing again took out the requisite ductility, and it was therefore necessary to again heat the wire and plunge it in the same manner as before. By doing this each time the wire was reduced two numbers of the gauge; there was no difficulty whatever in drawing it to any desired fineness, the only point necessary being that the wire must be heated sufficiently hot before plunging into cold water, or the wire would be still too hard. The colder the water the better the result."

It will thus be seen that sudden cooling increases the ductility and lessens the hardness of manganese steel—in other words, it anneals it, the opposite effect, of course, to that produced by sudden cooling in ordinary steel.

In this way Messrs. Hadfield furnished me with a few metres length of two sizes, No. 13 and No. 19 S.W.G. manganese steel wire. The wire was of two kinds, hard and soft. The latter was as flexible as soft iron wire; the former, on the contrary, was extremely rigid and hard. The *chemical composition* of the wire was as follows:—

Fe 84·96, Mn 13·75, C 0·85, Si 0·25, P 0·10, S 0·09 per cent.

Its *density* was 7·81, that of common steel wire being 7·717. Its *hardness* was such that it easily scratched steel, not hard-tempered. Exposed to the air manganese steel rusts rather more quickly than polished steel, but not nearly so quickly as iron. Careful experiments were made to determine—(1st) Its modulus of elasticity (Young's modulus) by direct stretching; (2nd) its breaking strain; (3rd) electric resistance; and (4th) its magnetic susceptibility. The results were communicated to the Royal Dublin Society in a paper read before that society in December last. These results, together with some additional experiments on the temperature variation of electric resistance, are briefly as follows:—

The modulus of elasticity was determined by suspending a length of 4 metres of the No. 19 wire (0·98 millimetre diameter) from a suitable clamp, the flexure of which under the maximum load used was tested and found inappreciable. An initial weight of 2 kilo-

* Paper read before the British Association Meeting at Manchester, September, 1887.

Digitized by Google

grammes was kept on to straighten the wire, and additions of 10 up to 40 kilogrammes were made. With the maximum load there was no set, the index returning accurately to zero on the removal of the weights. Three series of experiments were made, embracing some thirty observations, the mean of which gave 16,800 kilogrammes per square millimetre, or $1,680 \times 10^6$ grammes per square centimetre as Young's modulus for hard manganese steel wire. The soft manganese steel wire gave rather a lower modulus, namely, $1,671 \times 10^6$ gramme per square centimetre.

These numbers are lower than either steel or iron. Iron has a modulus of $1,861 \times 10^6$, and steel varies from 1881 up to $2,049 \times 10^6$ for pianoforte wire. Copper has a modulus of $1,195 \times 10^6$, and platinum wire of $1,700 \times 10^6$ grammes per square centimetre; so that manganese steel wire has about the same modulus of elasticity as platinum.

The breaking strain of the No. 19 annealed manganese steel wire I found to be 124lb., with an elongation of 4 centimetres in the length of 22 centimetres under trial. This corresponds to a breaking stress of 48·8 tons per square inch, or 768×10^4 grammes per square centimetre, with 18 per cent. elongation.

The *hard* manganese steel wire had a far higher tenacity and much less elongation. The same size, No. 19 wire (0·038in., or 0·98 millimetre diameter), broke at 280lb., equivalent to 110·2 tons per square inch. This is equivalent to $1,735 \times 10^4$ grammes per square centimetre. A second experiment gave 109·4 tons per square inch, and two independent tests, kindly made for me with an admirable dynamometer by Mr. Ivatt, engineer to the Great Southern and Western Railway Company, Dublin, at their works at Inchicore, yielded 107·9 and 110·7 tons per square inch. The elongation here was scarcely perceptible, being little over 1 per cent.

The breaking strain of ordinary steel wire varies from 54 to 63 tons per square inch. The best pianoforte steel wire is 150 tons per square inch. A comparative experiment I made with common pianoforte wire (0·027in. diameter) gave me 117 tons per square inch, or $1,851 \times 10^4$ grammes per square centimetre, and had the manganese wire been of the same gauge, its tenacity would probably have been about equal to this.

The profound change in the structure of this alloy produced by annealing through sudden cooling is remarkable, the breaking stress of the unannealed wire being more than double that of the annealed, and its intensity nearly eighteen times less.

I now come to the *electric resistance* of the wire. The length of the No. 19 wire I tried was 5 metres. This had a resistance of rather more than an ohm per metre. The resistance of the annealed and unannealed wire was exactly the same. Precisely speaking, the specific resistance of manganese steel at 15deg. C. is 0·000078 of an ohm, or 78 microhms per cubic centimetre. This is very high. The specific resistance of iron is 9,827 C.-G.-S. units, and of German silver 21,170 units per cubic centimetre. So that the resistance of manganese steel is 3½ times that of German silver. This high resistance and high melting point seemed to point to a useful application of this material for the construction of resistance coils for electric lighting and other purposes. I therefore determined how far the resistance was affected by change of temperature.

Some four metres of the wire were immersed in an oil bath and the resistance determined for every 10deg. C. rise of temperature up to 215deg. C. The resistance of 384 centimetres length of No. 19 wire at 15deg. C. was 4·22 ohms, or ·000078 absolute units per cubic centimetre—that is to say, 78 microhms per cubic centimetre. The resistance rose steadily up to 215deg. C., when it was 5·37 ohms, or 99·8 microhms per cubic centimetre, an increase of 27½ per cent., or 0·136 per cent. for 1deg. C.

This is a high increase, but not so high as iron. A specimen of commercial iron wire was tested for comparison. The resistance was found to be 13 microhms per cubic centimetre at 15deg. C., and rose to 26 at 215deg., an increase of 100 per cent., or a percentage increase of 0·5 for 1deg. C.

Nickel wire was also examined. The increase of resistance of nickel for increase of temperature I could not find in any tables. Possibly it has not hitherto been determined. Nickel wire (not pure) I found had a specific resistance at 15deg. C. 14·1 microhms for 1 cubic centimetre, increasing to 25·4; at 215deg. an increase of 80 per cent. for 200deg., or 0·4 per cent. for 1deg. C., not quite as large as iron.

German silver wire was also compared. The specimen tried had a specific resistance of 26 8 microhms for 1 cubic centimetre, and increased 7·8 per cent. for 200deg. C., or 0·04 per cent. for 1deg. C.

Hence the resistance of manganese steel is three times that of German silver, and its increase for temperature coefficient only one-third that of iron.

I have, in conclusion, to refer to some experiments I made last year to compare the coefficient of induced magnetism of manganese steel with that of soft iron. I had not then seen Dr. Hopkinson's well-known paper on the "Magnetisation of Iron," in which the magnetic induction in different kinds of manganese steel is given; and I may add that the experiments of Prof. Ewing on the magnetisation of iron in strong fields, which he proposed to extend and has since extended to manganese steel, were made subsequently to my attempt. The results I obtained did not differ very materially from those found by Dr. Hopkinson, the magnetic susceptibility of manganese steel in a powerful magnetic-field being about the same as that of ferric oxide in the same field.

Finally, a series of experiments were made to ascertain whether the presence of this percentage of manganese deprived the steel of other well-known physical properties.

As might be expected, manganese steel does not exhibit the magnetic tick or sound heard on the magnetisation of iron and steel, and which is well heard in nickel and most strikingly in cobalt. Nor, of course, does a bar of manganese steel show the slightest change of length on the passage of a magnetising current round it. A far more interesting question was whether this body would exhibit the anomalous expansion on cooling from a red heat and the sudden afterglow which I discovered some time ago occurred in iron, and notably in steel wire. The temperature at which the anomalous expansion and the afterglow occurs I have shown is coincident with the temperature when the magnetic state of iron and steel destroyed by a high temperature is resumed on cooling. Careful experiments with manganese steel wire established the fact that no trace of this anomalous deportment on cooling occurred with this substance. There was no sudden expansion, but a steady contraction; no afterglow, but a steady cooling from a white heat downwards.

Wires of various non-magnetic metals were also tried, platinum, copper, German silver, silver and gold. Not one of these exhibited the anomalous expansion nor the afterglow. Nickel wire, it is true, likewise did not exhibit it—at least, to any sensible extent; but the magnetic state of nickel is lost at a temperature of 330deg. C., considerably below a red heat. Cobalt wire would, I have no doubt, be found to exhibit phenomena analogous to steel; but I have not yet been able to obtain a specimen.

Here, then, we have some new and singular evidence of the close connection between the magnetic state and the molecular condition of a magnetic metal. At a certain critical temperature a magnetic metal loses its magnetic character, which is accompanied by a change of volume of specific heat, and of thermo-electric behaviour. These changes do not occur in non-magnetic metals.

In fine, when we remember that 13 per cent. of a more magnetic metal mechanically mixed with iron or steel produces but a slight change in the magnetic deportment, and then consider the profound change wrought by an alloy of steel with 13 per cent. of manganese (itself a fully magnetic body), interesting questions arise as to why chemical union should act in this manner. Manganese steel has about the same magnetic susceptibility in ferric oxide; German silver, in like manner—which is an alloy of the magnetic metal united with brass—is magnetically inert. More experiments are required on the magnetic behaviour of the different alloys of the magnetic metals. The effect of an alloy in increasing the electric resistance of a metal is well known; with manganese this effect is strikingly great. A steel whose percentage of manganese rises from 0·72 to 1·58, or say double, increases in resistance over 34 per cent.

The practical as well as theoretic interest of this alloy of steel is considerable. Obviously a body so tenacious, so hard, and so magnetically inert, ought to have many practical applications. Watches could be made non-magnetisable by springs of manganese steel. The time may not be far distant when a suitable alloy of manganese with steel may be economically and safely used in the construction of ironclad vessels, and anchors and chain cables, so that whilst keeping the strength of our modern ships of war we may return to the magnetic safety of wooden vessels.

ON THE MODE OF FORMATION OF HYDROGEN PEROXIDE DURING THE ELECTROLYSIS OF DILUTE SULPHURIC ACID.*

In a previous paper (*Wied. Ann.*, XXIV., p. 183, 1885) the author has investigated the mode in which the formation of S_2O_7, H_2O_2, and O_3 during the electrolysis of dilute sulphuric acid depends on the temperature, the duration and density of the current, and the degree of concentration of the acid. He found, as Berthelot had previously done, that H_2O_2 is formed only if the degree of concentration of the acid exceed 60 per cent. The author assumed it as obvious that the peroxides formed proceed from the anode, though owing to the form of the decomposing vessel this might be at first doubted. On the other hand, Dr. M. Traube, of Breslau, assumed (*Chem. Ber.*, XIX., p. 1,111, 1886) that H_2O_2 was never formed at the anode, but always at the cathode only, while the O_2 dissolved in the liquid—or in any

* Abstract of paper, "On our Knowledge of the Mode of Formation of Hydrogen Peroxide at the Anode during the Electrolysis of Dilute Sulphuric Acid," by Dr. Franz Richarz, of Berlin (*Wied. Ann*, XXXI., p. 912, 1887). Translated by Mr. E. F. J. Love. A communication from the author to the Electrolysis Committee of the British Association.

Digitized by Google

other way present—was reduced by 2 H to H_2O_2. The author has accordingly undertaken fresh experiments respecting the source of the H_2O_2 found by him.

The presence of small quantities of H_2O_2 in tolerably concentrated sulphuric acid, simultaneously with S_2O_7, could be proved by the decolorising of potassium permanganate ($KMnO_4$) and by the yellow coloration of titanium dioxide (TiO_2). If a greater quantity of H_2O_2 be present it was susceptible of further demonstration, under the conditions stated, by the formation of perchromic acid. The S_2O_7 was determined by the oxidation of ferrous sulphate.

The electrodes were placed in the legs of a U-tube; the anode was a thin platinum wire. With acid of strength exceeding 60 per cent. S_2O_7 and H_2O_2 showed themselves close to the anode after the current had been closed for a short period, while at the same time no trace of either was found near the cathode. After longer duration of the current the quantity of H_2O_2 at the anode became very considerable. But this only occurred when S_2O_7 had already shown its presence in the fluid.

The author has succeeded in showing that the H_2O_2 discoverable at the anode owes its origin to a purely chemical process. In a quantity of acid of about 40 per cent. strength a considerable amount of S_2O_7 was produced by electrolysis. This liquid, which contained no H_2O_2, was brought up to a strength of about 70 per cent by the addition of pure H_2SO_4, avoiding rise of temperature. At this point H_2O_2 was suddenly formed in the liquid, quite as rapidly as during the electrolysis of 70 per cent. acid. In sulphuric acid of this concentration, S_2O_7 cannot therefore exist without the formation in a short time of considerable quantities of H_2O_2, since atoms of active oxygen become separated from the S_2O_7 and oxidise H_2O to H_2O_2. That the oxidation of H_2O to H_2O_2 at the anode is not a primary process is made clear by the fact that SO_4—not O—is the anion, the active oxygen O is a secondary product.

Traube's theory of the constitution of H_2O_2 (l.c.) is finally refuted by the indisputable fact that the H_2O_2 makes its appearance at the anode, and is produced by the oxidation of H_2O.

ON ELECTROLYTIC CONVECTION CURRENTS.*

According to Helmholtz's theory of electrolysis and convection currents (the connection between which he demonstrated in the Faraday Memorial Lecture to the Chemical Society of London, April 5th, 1881), the existence of continuous currents in acidified water, under the action of electromotive forces less than about 1·5 Daniell, is explained by the occlusion of oxygen and hydrogen, especially the latter, in the electrodes, and by the charging of neutral oxygen dissolved in the liquid with negative electricity at the cathode; in consequence of which this oxygen either combines with two positive hydrogen atoms to form water or starts on a new migration as an anion towards the anode. Products demonstrably due to convection currents would *not* make their appearance in the liquid. The author is of opinion that H_2O_2 and H_2O may possibly be produced by the reduction of O_2, following the analogy of the mode of formation of H_2O_2 at the cathode by convection currents, shown by M. Traube to occur under certain conditions. In fact, after the current of a Daniell element has been passed for several days between platinum electrodes the presence of H_2O_2 in the liquid can be demonstrated, and it is even susceptible of quantitative estimation.

In order to answer the question, to what extent is the production of current due to the formation of H_2O_2? the strength of the convection-current was measured, and the quantity of H_2O_2 calculated which the current would have to yield during its continuance, in order that its production should depend only on the formation of H_2O_2. In this case a molecule of H_2O_2 is derived from every molecule of water which the current would decompose by regular electrolysis according to Faraday's law; we must, therefore, figure to ourselves the formation of H_2O_2 as occurring in some such way as the following:—Neutral oxygen $O\,{}^{-}_{-}\cdot{}^{+}_{+}O$† comes in contact with the cathode; it there gives up a positive unit of electricity, takes up a negative unit, and then combines with two positively charged hydrogen atoms to form hydrogen peroxide.

$$H+.-O-.+O-.+H.$$

But these same quantities of electricity would also be transferred from the cathode to the liquid, or *vice versâ*, if, as happens in the decomposition of a molecule of water, a +H is transformed into a −H, and escapes in combination with another +H as neutral hydrogen. In this way the total quantity of H_2O_2 which the current concerned could produce was calculated, and the quantity of H_2O_2 actually formed compared therewith.

Experiments with cathodes of different metals and an electromotive force of one Daniell showed that with annealed foil the occlusion of hydrogen at first takes the principal share in the production of the current; but if the charge of hydrogen on the cathode increases, the formation of H_2O_2 plays the chief part. If the metal of the cathode be previously fully charged with hydrogen, the convection current must be ascribed solely to the formation of H_2O_2, and the existence in the liquid of about $\frac{9}{10}$ths of the H_2O_2 calculated from the current strength may be proved.

Whether a definite electromotive force is needed for the formation of H_2O_2 has yet to be determined.

* Abstract of a paper on "Convection-Currents," by Dr. Franz Richarz, Verhandl. d. physik. Gesellsch. z. Berlin, 1887, No. 12. Translated by Mr. E. F. J. Love. A communication from the author to the Electrolysis Committee of the British Association.

† Misprinted in the original $O=\cdot{}^{+}_{+}O$.

After the reading by Dr. Lodge of the report of the Electrolysis Committee (for which see our issue of October 7th, page 464), Sir W. Thomson made the following remarks:—

Sir W. Thomson: A rule of the British Association exists according to which the report of a committee is not subject for discussion. That, of course, applies to the ordinary reports of ordinary committees; but this is not an ordinary report of an ordinary committee. It is a very extraordinary, and I think I may add a very extraordinarily valuable report. I am sure you will all agree with me in that opinion, and although we have placed second on the line that the section is to take the discussion on that report, I am sure you wish me to let nothing intervene between the reading of the report and the according to Prof. Lodge a vote of thanks for presenting so able a document to the association. It has been a most exhaustive philosophical treatment of all the aspects of the question, and seems to be the *beau ideal* of a report on a subject under investigation by a committee the main object of which is to promote research into all points that can be scientifically raised in reference to any part of the subject. And I must say I cannot think of any part of the question that has been touched upon by Prof. Lodge with reference to which the proper question has not been put in the proper scientific manner, to show how experimental research may come in and settle a question which by *a priori* reasoning we are unable to decide.

A METHOD OF TELEPHONIC COMMUNICATION BETWEEN SHIPS AT SEA.*

In February, 1883, while investigating at Berlin the experiments of Colladon and Sturm as to the velocity of sound through the waters of Lake Geneva, the thought occurred, "Why not make a practical use of water as a means of communicating between vessels at sea? Several methods were immediately devised, with the valuable suggestions of Dr. Koenig, Assistant in the Physical Laboratory of the Royal University, but actual experiment had to be deferred until a return to the United States in June of that year. At that time apparatus was prepared, and a course of experimentation has since been carried on to the present time, with more or less interruptions and more or less success. It may possibly prove interesting to learn of the methods employed and of the progress made. Further, perhaps, in the experiments something suggestive may be found which will enable inventors to follow out in detail the system proposed. As far as the writer knows, the thought, the experiments, and the whole scheme antedates all methods which have been proposed for fog signalling by telephone at sea.

Briefly, the plan was as follows:—A sound-producing apparatus was to be attached to each vessel, and to be worked under the surface of the water. In times of fog or night a code of signals would be produced by it which would be transmitted in all directions through the water, with a velocity four or five times that in the air. Each vessel, in addition to the sound-producing apparatus, would be provided with a sound-receiving apparatus, which would take up out of the water the signals arriving from neighbouring vessels. All of us remember when, as boys in swimming, how distinctly the sound of the striking of stones together under water was heard. Just so distinctly it is possible to send musical tones from one ship to another.

For steamships, the sound-producing apparatus was designed to be a steam fog-horn or whistle, specially constructed to sound under water, and to be heard at least from six to eight miles. From the nature of its tone it would be easily distinguishable from other sounds always more or less present under water, such as from breakers, waves, &c. With such whistles a Morse alphabet of long and short blasts and pauses was to provide a means of extended communication, while a simple universal code would indicate a ship's course. Since ignorance of the very presence of a ship, rather

* Paper read before the American Association for the Advancement of Science, at the New York Meeting, by Prof. Lucien J. Blake.

Digitized by Google

than incorrect estimates of her course, has been the principal cause of ocean collisions, the simple hearing of the sound would prove a most excellent general safeguard. Bell buoys were to have a second bell added under water, while lightships, light-houses, and any headlands might also be provided with submerged bells which could be rung from the shore, if necessary. Sailing craft, both large and small, would have bells, and since an ordinary locomotive bell can be heard, according to my experiments, at least two miles under water, such simple means would seem to afford sufficient limits for protection for such vessels.

As to the receiving apparatus, with which each vessel was to be provided, the original plan of 1883, and which has not been changed, was to employ some form of telephone acting as a transmitter under water and connected with a receiver within the vessel. The surface of the transmitter exposed to the water, and which must receive the sound waves, must be protected against ice, barnacles, heavy waves, &c. One design was that one or more vertical pipes in different parts of a ship were to extend from the vessel's interior through the hull, near the keel, and be open to the free admission of water at their lower ends ; their upper ends were to extend within the vessel a little way above the keel, and were to be plugged so that the water could not overflow into the vessel. These pipes would then provide columns of water always still, and would communicate directly with the water outside. Sound would then enter and pass up these pipes, and would encounter microphonic transmitters placed suitably in them. Wires from the transmitters could run to a small room, secluded wherever convenient in the ship, away from disturbing noises, and here telephone receivers would be placed, and observers stationed in night or fog.

For small craft it was found by my experiments that a pipe shaped much like an old-fashioned powder horn, with a thin flexible membrane stretched tightly across its broad end, made a successful receiver. With the small end made to fit the ear, and the diaphragm end only a few inches below water, the sound of a hand bell has been received nearly a mile distant. Colladon and Sturm used a somewhat similar receiver, and heard a heavy bell ten miles.

Such is the outline of the plan as conceived and experimented upon in 1883. In the long-distance experiments a locomotive bell or some form of gong was used ; while in the laboratory various automatic devices for producing sound under water were employed. First, it was necessary to devise the best form of receiving apparatus. Nearly all existing forms of telephones were first tried. The Bell receiver and the Blake transmitter will not work under water. The first success was obtained by a form of transmitter resembling the Ader. A cigar box cover, from its good resonant qualities, formed the diaparagm ; to this four small carbon blocks were screwed at the four corners of the square ; four cylinders 2in. long, of electric light carbon, formed the sides of the square and rested with their taper ends lightly on the blocks ; the carbons were put in series with a battery and Bell receiver. With this transmitter, with the help of E. W. Rockwood, Assistant in Chemistry, at Cornell, signals were transmitted and received between boats one-half mile apart on the Taunton River in 1883. The water, however, would spoil the contacts of the transmitter after a use of about 15 minutes. To obviate this the carbons were attached to the inside of a resonance box, which was then made water-tight. This. however, failed to make the transmitter markedly better. The transmitter was weighted to float at different depths, but in all positions, as regards the approaching sound waves, it received equally well. Up to about half-a-mile the signals from an ordinary dinner bell were distinctly heard. The higher overtones of the bell seemed to be quenched so that the sound came muffled. The experiments seemed to indicate that a transmitter dependent upon a variable contact might yet be made which would work with satisfaction. This line was consequently followed up for the next year or so. It might be stated that, later, with apparatus similar to that already described, signals were transmitted between boats a mile distant off Stone Bridge, near Newport, R.I., in the same summer of 1883, through a rough sea and in a dense fog. The latter attendant circumstances have nothing to do, of course, with the principles of sound transmission and reception, but gave encouragement that the method was independent of the state of the water outside.

From this time various forms of microphonic transmitters were constructed, and experiments on Long Island Sound and on the Wabash River, at Terre Haute, Indiana, were conducted as limited opportunities of time permitted.

In September, 1886, Mr. Jesse Kester, a young practical electrician, became interested, and with his valuable aid, the experiments have been carried on with many interruptions to the present summer.

One form of transmitter which has worked fairly well consists merely of a diaphragm having within itself the elements of a microphone. It is placed in simple voltaic circuit with a Bell receiver. This diaphragm is made out of hard carbon in granules about the size of the smallest shot. A paste is made of these with rubber cement, and this, in a mould and die under heat and pressure, becomes a hard, thin, elastic disc. The electrical resistance is very high, and can be altered according to the per cent. of rubber cement present. This disc or diaphragm takes up the sound vibrations excellently well out of the water, the rubber giving the requisite elasticity. The diaphragm vibrations produce corresponding varying pressures at the innumerable points of contact of the carbon granules. The action is, of course, similar to that of a multiple contact transmitter.

One difficulty, however, was found to lie in the gradual deterioration of elasticity under the action of salt water. Further, the brittleness of this diaphragm, especially when the carbon granules were comparatively large, or in large proportion to the cement, rendered it liable to rupture by a strong wave, or by any foreign substance striking it under water. A paste with celluloid was much tougher, and seemed a slight improvement. As a transmitter in the air this worked very nicely, and of course without the buzzing of the Blake. But no attempt was made to develop it further for this purpose.

To avoid this brittleness diaphragms of wood and metal were tried with one or more carbon buttons. These buttons, however, differed from the Blake or Edison in that the change of pressure which produced the undulatory currents operating the receiver did not occur at the surface where the button made contact with platinum or with other carbon pieces as in these latter, but the variations of pressure took place within the button itself. To do this these variable-pressure buttons were made as follows :—Fine granules of retort carbon were sorted to uniform size through a sieve with meshes about 900 to the square inch. These were then first plated with copper, then with silver, and thirdly with a thick coat of platinum. These different platings seemed necessary to make the platinum "stick" (adhere), so to express it. At the end of the platings there remained grains of high electrical resistance, exposing many points and irregularities for contacts. These grains, in different proportions, were mixed with rubber cement and a set of hard elastic balls, about the size of peas, and thick discs moulded out. These were included in a voltaic circuit with a Bell receiver, and the diaphragm rested lightly against them. Such an arrangement proved very sensitive to vibrations of the diaphragm under water. In the laboratory experiments a watch on a floating board could be heard through the water about 3ft. distant.

On the river, however, through a long distance, these did not seem sufficiently satisfactory. This difference in action between a long and a short distance, led to the thought that, as the advancing front of the sound wave is an arc, approaching in curvature nearer and nearer the tangent to its circle, a large diaphragm would receive more sonorous energy and thus probably prove more effective. This is the point to which the experiments have now been carried, and the next trials will be with a diaphragm 18in. square.

It is believed that sufficient has been done, however, to show that the complete solution of this interesting and valuable practical scheme will lie probably in the telephonic method just described or in some modification of it ; at least, by this method, in October, 1885, signals were transmitted and received 1½ miles on the Wabash River from a locomotive bell around three or four windings of the river, so that the operators were out of each other's sight, and the sound could not be heard through the air, yot could with fair distinctness through the telephone.

It is hoped that experimenters may find in the above methods and experiments enough to encourage further investigations, and with this end in view and from the fact that the writer is, for the present, by circumstances, turned to a different line of investigation, this article has been prepared, and the experiments thus for the first time made public.

COMPANIES' MEETINGS.

The Brazilian Submarine Telegraph Company (Limited).

The 28th ordinary general meeting of this Company was held at Winchester House, Old Broad-street, on the 2nd inst., under the presidency of the Right Hon. Viscount Monck.

The SECRETARY (Mr. Richard Collett) read the notice calling the meeting.

The CHAIRMAN reminded them that at their meeting a year ago he had to condole with them on a diminution of their receipts, telling them at the time that the depression of trade which had affected all the world more or less had at last affected their undertaking. He was glad to be able to state that during the half year to which the report now submitted referred the receipts had been larger than they had ever been since the Company was started. They amounted to over £100,000 for that period. That enabled the directors to declare the usual dividend of 6 per cent., and a bonus which brought up the dividend for the year to 7 per cent. That was a subject of congratulation to the Directors as showing the

Digitized by Google

prospects and condition of this undertaking, and he was happy to be able to inform them that the receipts since the close of the half year had continued to increase. The plant of the Company was all in good order. The reserve fund now amounted to £112,000, it having been increased to that amount during the last half year by the sum of £25,000. In their expenditure there had been an increase of £326, but that was accounted for in a great measure by the increase of the traffic, and also by the fact, which he had alluded to at the last meeting, that they had had to meet (which could not be done without some expenditure) attempts at creating competition. A shareholder had written to him asking him to say something about the African Direct Telegraph Company, in which the Brazilian Submarine Company was largely interested. He might say in general terms that that company had been in operation for only a very short time, that the receipts were improving, and that they were now about paying expenses. Therefore, they might hope that after a little while that would become a source of profit to the Company. But he must at the same time remind them that when they embarked in the African Direct Company they did it very much as a matter of strategy, to prevent a rival from coming into their district, and not as a pecuniary speculation. He concluded by moving the adoption of the report and the declaration of the dividend and bonus recommended.

The VICE-CHAIRMAN (Sir James Anderson) seconded the motion.

Mr. JOHN H. NEWMAN thought it would have been better, in view of the termination of their concession, if they had transferred the amount now proposed to be distributed as bonus to the reserve fund, so as to strengthen their position to meet the opposition which he felt sure they would encounter at the end of their term.

The CHAIRMAN said it was quite refreshing to him as Chairman to hear such observations, because many of the shareholders were probably aware that he had been fighting the cause of a larger reserve fund. He thought that Mr. Newman must have forgotten for the moment that the management had already duplicated their whole system of cables by means of an accumulated reserve fund—that was to say, with the exception of a very small portion of debenture capital which they were paying off by degrees. The reserve fund now, as he had already said, stood at £112,000. He therefore did not think the Directors would have been justified in withholding from the shareholders what they had legitimately earned this year in the way of bonus. He then put the resolution, which he declared carried unanimously.

On the motion of the CHAIRMAN, seconded by Mr. FREDERICK YOULE, Sir James Anderson was re elected a Director, as was also the Hon. W. St. John F. Brodrick, M.P., on the motion of the CHAIRMAN, seconded by Mr. H. D. GOOCH.

Mr. NEWMAN then proposed, and Mr. WM. HUNT seconded, a resolution for the re-election of Mr. Henry Dever and Mr. John Gano as auditors for the ensuing year, at a remuneration of £50 each, which was unanimously agreed to.

Dr. H. ELLERY TREWHELLA proposed a vote of thanks to the Chairman and Directors, and expressed a hope that they might be able hereafter to present the shareholders with an even more favourable record.

Mr. NEWMAN seconded the motion, which was unanimously passed.

The CHAIRMAN, in acknowledging the vote, said that he thought the duration of the meeting was the best test of the management of the Directors that could be given.

The meeting then separated.

Woodhouse and Rawson (Limited).

The statutory meeting of this Company was held on Wednesday, at 20, Bucklersbury, E.C., Lieut.-General Sir John Stokes, K.C.B, in the chair.

The SECRETARY having read the notice convening the meeting,

The CHAIRMAN said: Gentlemen, this is merely a statutory meeting; there is no formal business before the meeting. There are, however, one or two points that may be interesting to you to hear. Mr. Ashby has been elected a Director; he represents a very large number of shareholders. I regret to tell you of the death of Mr. Woodhouse. This took place on September 21st, after a long illness. As Mr. Woodhouse has not attended to the business for a very long time it will make no difference in carrying it on. The Directors wish to express their regret at his death. That is the only communication I have to make to you. I do not know whether any gentleman wishes to ask any question.

Mr. GEORGE SMITH: I think, Mr. Chairman, as shareholders, we would like to know something of how the business is going on, whether all the shares have been taken up, whether the work is progressing satisfactorily, and whether we may look forward in due course to our 10 per cent. dividend. Any information you can give us will be very acceptable to the shareholders, I am sure.

The CHAIRMAN: We are doing our business, and carrying out the purposes of the Company announced in the prospectus. The whole of the shares have been taken up. We have already business in hand which justifies us in hoping to be able to declare a dividend when the time comes. It is early yet, and it is impossible to say whether it will be 10 per cent., or what it will be.

Mr. SMITH: I think, Sir, it was expressed in the prospectus.

The CHAIRMAN: Oh, yes. There has been an increase in the sale of electrical supplies during the last two months that has been considerably greater than the corresponding period of last year, and that two months is the period we have been working. Arrangements have been made under which our lamps are being made and sold on satisfactory terms. Our position as a manufacturing company has considerably improved, and we are receiving large orders. I think that is a satisfactory statement to make.

Mr. SMITH: I suppose the litigation is at an end?

The CHAIRMAN: We have no litigation.

Mr. RAWSON: I will explain that the litigation is at an end excepting this, that we have the right to appeal to the House of Lords for a certain length of time, and, of course, it depends how matters go for the next few months whether we appeal or not. If we appeal it has nothing to do with Woodhouse and Rawson (Limited), it has only to do with Woodhouse and Rawson.

Mr. SMITH: It would be a great boon to this Company if we could make lamps in this country. They are being made abroad.

Mr. RAWSON: Yes, no doubt.

The CHAIRMAN: I think that is all, gentlemen, and I need not detain you any longer.

Mr. SMITH: Shall we have half-yearly meetings after this?

The CHAIRMAN: Annual meetings.

Mr. SMITH: When will the next annual general meeting be held?

The CHAIRMAN: I cannot say; there is nothing arranged for that. In October next year probably, when the accounts will be made out.

The proceedings then terminated.

CITY NOTES, &c.

BRAZILIAN SUBMARINE TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 28st October amounted to £4,173.

CUBA SUBMARINE TELEGRAPH COMPANY.—The number of messages passing over the lines of this company during the month of October was 3,416, estimated to produce £2 900, against 2,782 messages, producing £2,413, in the corresponding month of last year. The traffic receipts for the month of July, estimated to produce £2,600, realised £2,607.

DIRECT SPANISH TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the month of October amounted to £2,276, against £2,038 for the corresponding period of last year.

EASTERN TELEGRAPH COMPANY.—The traffic receipts of this company for the month of October, amounted to £53,089, and to £49,374 in the corresponding period of 1886.

EASTERN EXTENSION, AUSTRALASIA, AND CHINA TELEGRAPH COMPANY.—The traffic receipts of this company for the month of October, amounted to £40,018, and to £37,185 in the corresponding period of 1886, bing an increase of £2 833.

WESTERN AND BRAZILIAN TELEGRAPH COMPANY.—The traffic receipts of this company for the week ended 28th October, 1887, were £3,362, after deducting the "fifth" of the gross receipts payable to the London Platino-Brazilian Telegraph Company.

WEST INDIA AND PANAMA TELEGRAPH COMPANY.—The estimated traffic receipts of this company for the half-month ended 31st October are £2,742, as compared with £2,053 in the corresponding period of 1886.
